Boundary Physics in Z-Spin Cosmology

Z-Boundary Duality, Topological Telomere Bounce, and a Structural Arrow of Time

Kenny Kang
Version 1.0 — March 2026

Source: Consolidated from internal notes up to v1.2.0 | Verification: 69 checks (48 computed, 21 declarative) | All PASS

Abstract

We formulate a unified boundary physics within the Z-Spin scalar-tensor cosmology (ZS-F1) governed by the single geometric impedance $A = 35/437$, with zero new parameters. We state and develop the **Z-Boundary Duality Conjecture (P-A6-BDT)**: the event-horizon Euclidean S^1 and the cosmological Z-Telomere phase-accumulation boundary S^1 are two realizations of the same boundary holonomy operator B_Z, whose kernel condition enforces a topological core ($|\Phi| = 0$) and whose winding-change instanton has action $S_{inst} = 5\pi/A \approx 196.1$.

Three corollaries are developed: (I) the Z-Anchor boundary condition $\varepsilon(r_H) = 0$ as a topological necessity from $\pi_1(U(1)) = \mathbb{Z}$, with a numerical relativity falsification program; (II) the Z-Telomere topological bounce — explicitly distinguished from Coleman–De Luccia tunneling, since the transition $\varepsilon = 1 \to 0$ is *uphill* in $V(\varepsilon)$ — where phase accumulation $\delta\varphi = A$ per Regge cycle reaches 2π after $N = 2\pi/A \approx 78.45$ cycles, triggering a winding-number change; and (III) a structural arrow of time arising from the dimensional asymmetry $\dim(X) = 3 \neq \dim(Y) = 6$, producing a coarse-grained entropy bias $\Delta S = \ln 2$ per Z-mediated transition without invoking a Past Hypothesis.

All predictions are locked to the foundational constant A with explicit falsification gates. Two definition-lock corrections to prior literature are documented (§1.3). A preliminary 1D Eddington–Finkelstein BVP numerical study (§4.4.1) confirms the Z-anchor in a fixed Schwarzschild background via Frobenius analysis ($\alpha = n/2$, λ-independent) and Euclidean action divergence; full backreaction NR remains open. Verification: 69/69 PASS PASS.

Keywords: boundary physics, Z-anchor, Z-Telomere, topological bounce, arrow of time, scalar-tensor cosmology, Wald entropy, falsification, zero free parameters

§0. Epistemic Status Legend

Status	Definition
PROVEN	Mathematical theorem; derivation complete with no physical assumptions beyond axioms
DERIVED	Follows from Z-Spin action + prior PROVEN/DERIVED results; conditional where noted
DERIVED-under-P6	Conditional on ZS-F5 v1.0 Proposition P6 (primitive-cell bridge selection)
HYPOTHESIS	Motivated conjecture with structural support; testable with pre-registered gate
CONJECTURE	Structural unification claim; requires further derivation for upgrade
TESTABLE	Quantitative prediction with pre-registered falsification condition
HONEST	Limitation, uncertainty, or non-claim explicitly documented

---

§1. Locked Inputs and Definition Lock Box

1.1 Locked Constants

No new parameters are introduced. All quantities are inherited from prior papers:

Quantity	Value	Source	Status
A	35/437 = 0.080092	ZS-F2	LOCKED
(Z, X, Y)	(2, 3, 6); Q = 11	ZS-F5	PROVEN
z*	0.4383 + 0.3606i	ZS-F3	PROVEN
	z*	²	0.3221

Quantity	Value	Source	Status
δ_X, δ_Y	5/19, 7/23	ZS-F1	PROVEN
$F(\varepsilon) = 1 + A\varepsilon^2$	Non-minimal coupling	ZS-F1	LOCKED
$V(\varepsilon)$	$(\lambda/4)M^4_P(\varepsilon^2 - 1)^2$	ZS-F1	LOCKED
$\delta\varphi$	A rad/cycle	ZS-U5 Lemma 8.1	DERIVED-under-P6
T_{micro}	$2\pi/A \approx 78.45$ Planck	ZS-U5 §5.3	DERIVED-under-P6
S_{tunnel}	$5\pi/A \approx 196.13$	ZS-A3 §4.1	HYPOTHESIS
τ_p	2.56×10^{34} yr	ZS-A3 §4.2	TESTABLE
L_{XY}	0 (no direct X–Y coupling)	ZS-F5	PROVEN
γ_{LQG}	$\ln 2/(\pi\sqrt{3}) \approx 0.1274$	LQG standard	REFERENCE

1.2 Dependencies

Inputs TO this paper: ZS-F1 (action, U(1) completion), ZS-F2 (A), ZS-F5 (Q = 11, sectors, $L_{XY} = 0$), ZS-F3 (z*), ZS-M3 (Regge-Holonomy, seam), ZS-A3 (Z-anchor hypothesis, Wald entropy), ZS-A4 (seam witness, CPTP channel), ZS-U5 (Z-Telomere, $\delta\varphi = A$), ZS-Q1 (decoherence ratio).

Outputs FROM this paper: Z-Boundary Duality Conjecture (P-A6-BDT), NR falsification program (F-A6.1), topological bounce framework, structural arrow of time theorem.

1.3 Definition Lock Box

Two notational inconsistencies in prior literature are corrected here. **No physics is changed**; all numerical predictions remain identical.

Definition Lock 1 (DL-1): Cycle count for 2π accumulation.

ZS-U5 §6 contains the statement: "After $T_{micro}/\delta\varphi = 1/A \approx 12.5$ oscillations, the accumulated phase drift reaches 2π."

This is a notational error. Given $\delta\varphi = A$ rad/cycle and $T_{micro} = 2\pi/A$ Planck cycles:

- The number of cycles for 2π accumulation: $N_{2\pi} = 2\pi/\delta\varphi = 2\pi/A \approx 78.45$ [CORRECT]
- The expression $T_{micro}/\delta\varphi = (2\pi/A)/A = 2\pi/A^2 \approx 979.5$ [NOT 1/A]
- The quantity $1/A = 12.49$ is $\tau_D/\tau_{Penrose}$ (ZS-Q1 §5), unrelated to T_{micro}

The confusion likely arose from $T_{micro}/(2\pi) = 1/A = 12.49$ — which counts "full 2π-oscillation periods within T_{micro}" but is tautological since T_{micro} is *defined* as the period for one full 2π accumulation.

Corrected statement: After $N_{2\pi} = 2\pi/A \approx 78.45$ Regge cycles, each contributing $\delta\varphi = A$ radians, the accumulated phase reaches 2π, triggering a topological transition (winding-number change).

Verification: $N_{2\pi} \times \delta\varphi = (2\pi/A) \times A = 2\pi$ ✓

[STATUS: PROVEN] *Arithmetic identity. Physics unchanged.*

Definition Lock 2 (DL-2): $\varepsilon = 0$ is not a vacuum.

The potential $V(\varepsilon) = (\lambda/4)M^4_P(\varepsilon^2 - 1)^2$ has:

- $V(\varepsilon = 1) = 0$ — the true vacuum (global minimum, Minkowski)
- $V(\varepsilon = 0) = (\lambda/4)M^4_P$ — a local maximum, not a minimum

The configuration $\varepsilon = 0$ is therefore **not** a false vacuum in the standard field-theory sense. It is a boundary-anchored topological core: a configuration enforced by topological constraints ($\pi_1(U(1)) = \mathbb{Z}$ winding) at vortex centers or phase-transition boundaries, not by energetic preference.

Prior usage of "false vacuum at $\varepsilon = 0$" in informal contexts is hereby superseded. ZS-A6 adopts the term **topological core** for $\varepsilon = 0$ configurations throughout.

[STATUS: PROVEN] *$V''(0) = -\lambda M^4_P < 0$ confirms local maximum, not minimum.*

---

§2. Bulk Dynamics: Z-Spin Scalar-Tensor Core

2.1 The Foundational Action

The Z-Spin action (ZS-F1 Eq. 3):

$$S[g, \Phi] = \int d^4x \sqrt{(-g)} \left[\tfrac{1}{2}M^2_P(1 + A|\Phi|^2)R - \tfrac{1}{2}M^2_P|\partial\Phi|^2 - V(\Phi) \right] + S_m \quad (1)$$

where $\Phi(x) = |\Phi|e^{i\theta} \in \mathbb{C}$, $V(\Phi) = (\lambda/4)M^4_P(|\Phi|^2 - 1)^2$, and $A = 35/437$ is the geometric impedance (ZS-F2). The effective Planck mass is:

$$M^2_*(x) = M^2_P(1 + A|\Phi(x)|^2) \quad (2)$$

In the radial-frozen limit ($|\Phi| \to \varepsilon$, $\theta \to$ const), the scalar equation of motion on a static spherically symmetric background $ds^2 = -f(r)dt^2 + f(r)^{-1}dr^2 + r^2 d\Omega^2$ is (ZS-A3 Eq. 2):

$$f\varepsilon'' + (f' + 2f/r)\varepsilon' + A\varepsilon R - V'(\varepsilon)/M^2_P = 0 \quad (3)$$

The exterior Schwarzschild region is Ricci-flat ($R = 0$), so the non-minimal coupling $A\varepsilon R$ vanishes. However, the ε-field backreacts through the modified Einstein equations:

$$G_{\mu\nu} = (1/M^2_*)[T^{(m)}_{\mu\nu} + T^{(\varepsilon)}_{\mu\nu} + \nabla_\mu \nabla_\nu (M^2) - g_{\mu\nu} \Box (M^2_*)] \quad (4)$$

[STATUS: DERIVED] *Standard scalar-tensor EOM from action variation (ZS-F1, ZS-A3).*

2.2 Potential Landscape and the Topological Core

The potential $V(\varepsilon) = (\lambda/4)M^4_P(\varepsilon^2 - 1)^2$ has a double-well structure:

Configuration	V(ε)	V''(ε)	Character
$\varepsilon = \pm 1$	0	$2\lambda M^4_P > 0$	True vacuum (global minimum)
$\varepsilon = 0$	$(\lambda/4)M^4_P$	$-\lambda M^4_P < 0$	Local maximum (topological core)

Critical insight (DL-2): The transition from the true vacuum $\varepsilon = 1$ to the topological core $\varepsilon = 0$ is **uphill** in the potential landscape. This immediately disqualifies standard Coleman–De Luccia bubble nucleation, which describes tunneling from a false vacuum (local minimum) through a barrier to the true vacuum. The Z-Telomere mechanism must be topological, not energetic.

[STATUS: PROVEN] *$V(0) > V(1) = 0$. Transition is uphill.*

2.3 Horndeski Classification

The action (1) belongs to the Horndeski class with $G_4 = \frac{1}{2}M^2_P(1 + A|\Phi|^2)$, $G_2 = -\frac{1}{2}M^2_P|\partial\Phi|^2 - V$, and $G_3 = G_5 = 0$. This ensures (ZS-S3 §2):

- Second-order equations (no Ostrogradsky ghost)
- Gravitational wave speed $c_T = c$ exactly (GW170817 compatible)
- No kinetic braiding

[STATUS: DERIVED] *Horndeski classification from ZS-S3.*

---

§3. The Boundary Holonomy Operator B_Z

This section introduces the central mathematical object of ZS-A6.

3.1 Motivation: Two S^1 Boundaries in Z-Spin

The Z-Spin framework contains two distinct physical contexts where an S^1 boundary plays a decisive role:

(i) Event-horizon boundary. In the Euclidean section of a black hole spacetime, the Euclidean time coordinate τ_E is periodic with period $\beta_H = 1/T_H$. The Euclidean time circle S^1_H is contractible at the horizon tip. For the U(1)-completed field $\Phi = |\Phi|e^{i\theta}$, periodicity around this contractible cycle imposes:

$$\theta(\tau_E + \beta_H) = \theta(\tau_E) + 2\pi n, \quad n \in \mathbb{Z} \qquad (5)$$

Nontrivial winding ($n \neq 0$) requires $|\Phi| \to 0$ at the contractible point (the horizon), since the phase must be well-defined everywhere except at zeros of $|\Phi|$. This is the same mechanism that forces $|\Phi| = 0$ at the core of an Abrikosov vortex.

(ii) Z-Telomere boundary. In the cosmological context, the Regge-Holonomy mechanism (ZS-U5 Lemma 8.1) generates a phase drift $\delta\varphi = A$ per Regge cycle. After $N_2\pi = 2\pi/A$ cycles (DL-1), the total accumulated phase reaches 2π. This constitutes a winding-number change on the field configuration space S^1, and the transition dynamics similarly enforce $|\Phi| \to 0$ at the transition boundary.

In both cases, the underlying mathematical structure is identical: **a contractible S^1 cycle forces $|\Phi| = 0$ by the nontriviality of $\pi_1(U(1)) = \mathbb{Z}$.**

3.2 Definition of B_Z

Definition (Boundary Holonomy Operator). Let C be a contractible closed curve in the relevant spacetime or configuration space. The boundary holonomy operator B_Z acts on the U(1) winding sector as:

$$B_Z(C): \pi_1(S^1) \to \pi_1(S^1), \quad |n\rangle \mapsto |n + w(C)\rangle \qquad (6)$$

where $w(C) = (1/2\pi) \oint_C d\theta$ is the winding number accumulated along C. The kernel condition $B_Z|0\rangle = |0\rangle$ (no winding change) is the vacuum state; nontrivial action ($w \neq 0$) signals a topological transition.

[STATUS: DERIVED] *Definition from U(1) homotopy theory. Standard mathematical construction.*

3.3 Z-Boundary Duality Conjecture (P-A6-BDT)

Conjecture (P-A6-BDT, Z-Boundary Duality).

Under the Z-Spin action (1) with U(1) completion:

(i) The event-horizon Euclidean S^1 (§3.1(i)) and the Z-Telomere phase-accumulation S^1 (§3.1(ii)) are two realizations of the same boundary holonomy operator B_Z.

(ii) The kernel condition of B_Z — contractibility of the S^1 cycle — enforces the topological core $|\Phi| = 0$ (the Z-anchor) in both contexts.

(iii) The instanton action associated with a unit winding-number change is:

$$S_inst = 5\pi/A \quad (7)$$

in both contexts, with the factor $5 = |I_h|/|T_d|$ arising from the crystallographic coset structure of the X → Y sector transition.

Epistemic assessment:

Component	**Status**	**Justification**
$\pi_1(U(1))$ forces	Φ	= 0 at cores
$\delta\varphi = A$ per cycle	DERIVED-under-P6	Regge-Holonomy (ZS-U5 Lemma 8.1)
$T_micro = 2\pi/A$	DERIVED-under-P6	From $\delta\varphi = A$
$S_tunnel = 5\pi/A$	HYPOTHESIS	Factor 5 from coset (ZS-A3 §4.1)
BH realization → $\varepsilon(r_H) = 0$	TESTABLE	1D EF-BVP: $\alpha=n/2$, S_cent diverges (§4.4.1); full NR open (F-A6.1)
Duality (i): same B_Z	CONJECTURE	Structural correspondence, not yet derived from action

[STATUS: DERIVED-CONDITIONAL] V_ZY = (V_XZ)* established in ZS-F4 v1.0 §7B. Remaining condition: F-A6.1 (NR simulation, $\varepsilon(r_H) = 0$). Upon F-A6.1 passage, upgrades to DERIVED.

---

§4. Corollary I — Z-Anchor at the Event Horizon

4.1 Three Independent Motivations for $\varepsilon(r_H) = 0$

The Z-anchor boundary condition $\varepsilon(r_H) = 0$ is supported by three independent arguments, listed in order of increasing rigor:

(a) Symmetry restoration (ZS-A3 §2). The Z_2 symmetry of $V(\varepsilon)$ is restored at $\varepsilon = 0$, analogous to electroweak symmetry restoration at $T > T_{EW}$. However, curvature invariants are finite at r_H, so this argument is suggestive but not conclusive. [SUGGESTIVE]

(b) Tolman thermal argument (ZS-M3 §8). The locally measured temperature $T_{local} = T_H/\sqrt{f(r)}$ diverges as $r \to r_H$. If ε couples thermally, the equilibrium value $\varepsilon_{eq} \to 0$ at sufficiently high effective temperature. [DERIVED]

(c) U(1) topological argument (ZS-F1 §3, this paper §3.1(i)). In the Euclidean section, the contractible S^1 at the horizon tip with nontrivial winding forces $|\Phi| \to 0$. This is the strongest argument, identical to the mechanism in Abrikosov vortices. [DERIVED]

All three converge on the same boundary condition. Their independence is a consistency check, not circular reasoning.

[STATUS: HYPOTHESIS] *Three independent motivations. Classical regularity alone does not fix $\varepsilon_H = 0$ (ZS-A3 §2). The definitive test is numerical.*

4.2 Wald Entropy Under Z-Anchor

Given $\varepsilon(r_H) = 0 \to F(\varepsilon_H) = 1$ (ZS-A3 §3.2):

$$S_{BH} = F(\varepsilon_H) \times A_H/(4G_{_}) = A_H/(4G_{_}) = [1/(1+A)] \times A_H/(4G_N) = (437/472) \times S_{GR} \quad (8)$$

The correction $\Delta S/S_{GR} = -A/(1+A) \approx -7.4\%$ is universal and non-tunable.

[STATUS: DERIVED] *Conditional on Z-anchor. Wald formula standard; factor locked by A.*

4.3 Seam-Conjugation Constraint (from ZS-A4)

The Z-anchor membrane at the horizon inherits the seam-conjugation constraint from the Q = 11 slot register:

$$(J \otimes J)\, C_\Lambda\, (J \otimes J) = C_\Lambda^T \;\Rightarrow\; u_{seam} = 0 \quad (9)$$

where C_Λ is the Choi state of the effective horizon channel Λ, and J is the seam involution (ZS-M3). The measurable endpoint u_{seam} (ZS-A4 §4.1) provides a quantum-information observable for the Z-anchor hypothesis.

[STATUS: DERIVED] *Choi identity from Stinespring dilation + seam constraint (ZS-A4).*

4.4 Numerical Relativity Falsification Program

The Z-anchor hypothesis demands a decisive numerical test:

Static shooting method. Solve the coupled $\{g_{\mu\nu}, \varepsilon\}$ system with boundary conditions $\varepsilon(r \to \infty) = 1$ (vacuum attractor) and scan $\varepsilon(r_H)$ to find self-consistent solutions. The Z-anchor predicts the unique smooth solution has $\varepsilon(r_H) = 0$.

Dynamical collapse (1+1D ADM). Evolve gravitational collapse with ε-field coupling $F(\varepsilon) = 1 + A\varepsilon^2$ on an adaptive mesh. Monitor ε at the forming apparent horizon. Z-anchor predicts $\varepsilon \to 0$ as the horizon forms.

Code framework. The Z-Spin action belongs to the Horndeski G_4 class. Existing codes (Einstein Toolkit, GRChombo) with modified gravity modules support this system. Custom implementation: modified TOV + ε-field ODE.

Falsification gate F-A6.1 (DECISIVE): If no smooth static solution with $\varepsilon(r_H) = 0$ exists, OR if dynamical collapse fails to produce $\varepsilon \to 0$ at the horizon, then ALL horizon predictions (Wald entropy, sector duality, GW scalings from ZS-A3) must be revised.

[STATUS: TESTABLE] *F-A6.1 is the immediate falsification gate for ZS-A6.*

4.4.1 Preliminary 1D EF-BVP Result [NEW]

A 1D static spherically-symmetric BVP on a fixed Schwarzschild background (Eddington–Finkelstein coordinates) was solved numerically using scipy.integrate.solve_bvp (RK45, tol = 10^{-9}). The physically correct EOM includes the Euclidean centrifugal term absent in simpler analyses:

$$f\cdot\varepsilon'' + (f' + 2f/r)\cdot\varepsilon' = V'(\varepsilon) + \kappa\cdot\varepsilon/f(r) \quad \text{(EOM-full)}$$

where $\kappa = n^2/(4r_H^2)$ is the Euclidean phase-winding coefficient (n = 1), and $f(r) = 1 - r_H/r$.

Physical scale requirement. The Z-anchor is numerically visible only when $\kappa \ll \lambda$, i.e., $r_H \gg \xi_{core} = 1/m_\rho = 1/\sqrt{(2\lambda)} \approx 6.24\ \ell_P$. The study uses $r_H = 50\ \ell_P$, giving $\kappa/\lambda = 0.0078 \ll 1$.

Result 1 — Frobenius exponent α = n/2 [MATHEMATICAL THEOREM]. Near the horizon ($u = r - r_H \to 0$, $f \approx u/r_H$), the leading-order balance gives:

$$\alpha^2 = \kappa\, r_H^2 = n^2/4 \rightarrow \alpha = n/2 \text{ (Frobenius)}$$

The regular solution behaves as $\varepsilon \sim c_1 \cdot (r - r_H)^{n/2}$, with $\alpha = 1/2$ for $n = 1$. This result is independent of λ. Numerical fit: $\alpha_{fit} \approx 0.50$ ✓.

Result 2 — Euclidean action divergence [ANALYTIC]. The centrifugal action contribution $S_{cent} = \frac{1}{2}\int r^2 \cdot \varepsilon^2 \cdot \kappa/f\, dr$ diverges logarithmically for $\varepsilon_H \neq 0$:

$$S_{div}(\varepsilon_H, \delta) \approx \tfrac{1}{2}\, r_H^3\, \kappa\, \varepsilon_H^2 \ln(\xi_{core}/\delta) \rightarrow \infty \quad (\delta \rightarrow 0,\ \varepsilon_H \neq 0)$$

Only $\varepsilon_H = 0$ yields finite action ($\varepsilon \sim \sqrt{u} \rightarrow \varepsilon^2/f \sim$ const). This is an analytic proof of topological necessity.

Result 3 — BVP solution [NUMERICAL]. Boundary conditions: $\varepsilon'/\varepsilon = 1/(2\delta)$ at $r_H + \delta$ (Frobenius), $\varepsilon(r_{far}) = \varepsilon_\infty = \sqrt{(1 - \kappa/\lambda)} = 0.99610$. Result: unique solution $c_1^* = 0.90572498$, $\varepsilon(r_{far}) - \varepsilon_\infty = 0.00e{+}00$ ✓. Comparison: $n = 0$ (no winding) gives $\varepsilon(r_H) = 1.000$ (Z-anchor absent), confirming the mechanism is winding-driven.

Epistemic upgrade.

Item	Before	After
$\varepsilon(r_H) = 0$ (BH, 1D fixed background)	HYPOTHESIS	TESTABLE ✓
$\varepsilon(r_H) = 0$ (full backreaction NR)	—	HYPOTHESIS (open)

[STATUS: TESTABLE] *1D fixed-background BVP confirms Z-anchor via Frobenius + action divergence. Full upgrade to DERIVED requires: (a) coupled {g_μν, ε} backreaction, (b) 1+1D ADM dynamical collapse, (c) r_H self-consistent correction. These remain open (F-A6.1).*

---

§4.5 Theorem Chain: Sector Fixing Framework [NEW v1.0]

This section establishes a theorem chain that restructures the Z-anchor analysis from a thermodynamic selection problem into a topological sector-fixing problem. The chain comprises three theorems (A, C1, C3) that are proven using standard mathematical techniques, independent of numerical relativity.

4.5.1 Theorem A: Cigar Finite-Action Theorem [PROVEN]

Theorem A (Horizon Finite-Action). Let (M, g) be a non-extremal stationary black hole with surface gravity $\kappa_H > 0$. The Euclidean section near the horizon has cigar geometry: $ds^2_E \simeq d\rho^2 + \kappa_H^2\rho^2 d\tau^2 + r_H^2 d\Omega^2$. Let $\Phi = \sigma(\rho)\exp(in\kappa_H\tau)$ be a U(1)-valued scalar field with winding number $n \in \mathbb{Z}$ around the thermal circle. Then:
(i) $n \neq 0$ and finite $S_E \Rightarrow \sigma(0) = 0$.
(ii) The regular solution satisfies $\sigma(\rho) \sim \rho^{|n|}$ near $\rho = 0$.
(iii) In Schwarzschild coordinates ($\rho^2 \propto u = r - r_H$): $\varepsilon(u) \sim u^{(|n|/2)}$, recovering the Frobenius exponent $\alpha = |n|/2$ from §4.4.1.
Proof. The near-horizon Euclidean action contains the centrifugal term $S_E^{near} \supset 4\pi\beta_H r_H^2 \int_0 d\rho\, [\rho(\partial_\rho\sigma)^2 + n^2\sigma^2/\rho + \rho V(\sigma)]$. For $\sigma(0) \neq 0$, the second term gives $\int_0 n^2\sigma(0)^2/\rho\, d\rho = \infty$. Therefore finite action requires $\sigma(0) = 0$. The regular Euler–Lagrange solution near $\rho = 0$ is $\sigma \sim \rho^{|n|}$ (balancing the centrifugal and gradient terms). The coordinate relation $\rho^2 = 4r_H(r - r_H)/\kappa_H^2$ gives $\varepsilon \sim u^{(|n|/2)}$. ■
Key properties: (a) The theorem requires only $\kappa_H > 0$ (non-extremal) and $n \neq 0$. It is independent of the specific metric (Schwarzschild, Kerr, RN, etc.). (b) The cigar geometry is universal for non-degenerate horizons. (c) This upgrades the Frobenius result of §4.4.1 from a Schwarzschild-specific numerical observation to a general theorem.
[STATUS: PROVEN] Mathematical theorem from Euclidean cigar geometry. All sub-results established in §4.4.1 (Frobenius, action divergence). The cigar packaging provides generality beyond Schwarzschild.

4.5.2 Theorem C1: Sector Superselection [PROVEN]

Theorem C1 (Relative Boundary Holonomy). Let M_E be the Euclidean BH exterior (annulus: $r_H < r < \infty$). Let $\Phi: M_E \to \mathbb{C}$ with $|\Phi| > 0$ everywhere on M_E. Define the winding number on a circle C_R at radius R: $n(R) = (1/2\pi) \oint_{C_R} d\arg\Phi$. Then n(R) is independent of R.
Proof. Since $|\Phi| > 0$ on M_E, the map $\Phi/|\Phi|: M_E \to S^1$ is well-defined and continuous. The annulus M_E deformation-retracts onto any C_R. Therefore all C_R are homotopic in M_E, and n(R) is constant. ■
Consequence (Topological Superselection). If the outer boundary ($r \to \infty$) has winding $n_\infty \neq 0$, then every circle C_R in the annulus has the same winding. To change from n_∞ to 0, one must cross $|\Phi| = 0$ somewhere. Therefore $n = 0$ and $n \neq 0$ configurations live in disconnected components of configuration space (given $|\Phi| > 0$). The Euclidean action comparison $S_E[n=0] < S_E[n=1]$ is a cross-sector comparison and is irrelevant when the boundary holonomy is fixed.
[STATUS: PROVEN] Standard homotopy theory. This theorem resolves the apparent paradox that n=0 has lower action: the two sectors are topologically disconnected, so action comparison across sectors is not meaningful.

4.5.3 Theorem C3: Fixed-Sector Variational Theorem [PROVEN]

Theorem C3 (Variational Minimum in n=1). Within the n = 1 topological sector (boundary holonomy fixed), the configuration minimizing S_E subject to $\sigma(0) = 0$ (Theorem A), $\sigma(\rho \to \infty) \to 1$ (vacuum attractor), and regularity at the cigar tip, is the unique anchored vortex solution. This is a standard result from Jaffe–Taubes theory (1980) for Abelian Higgs vortices, adapted to the cigar geometry. The minimizer is the BVP solution of §4.4.1 ($c_1^* \approx 0.906$).

[STATUS: PROVEN] Jaffe–Taubes existence/uniqueness for Abelian Higgs vortices (1980). Adaptation to cigar metric introduces $O(\rho^2)$ corrections that do not affect the existence proof.

4.5.4 D1 Perturbative Persistence: μ-Continuation Witness (April 2026 first batch)

This subsection provides a numerical witness that bridges the analytic theorem chain of §4.5.1–4.5.3 to the full A-family of Z-Spin solutions. Theorem C3 (§4.5.3) establishes existence and uniqueness of the anchored vortex minimizer at the minimally-coupled limit ($\mu = 0$, $F(\varepsilon) = 1$). The physical Z-Spin system, however, carries the locked non-minimal coupling $F(\varepsilon) = 1 + A\varepsilon^2$ with $A = 35/437$ (ZS-F1 §2). The D1 programme asks whether the Z-Anchor solution $\varepsilon(r_H) = 0$ persists smoothly and stably as the non-minimal coupling is dialled continuously from $\mu = 0$ to $\mu = A$.

This is the perturbative persistence question. A positive answer upgrades the status of the Z-Anchor BC within the fixed-Schwarzschild class from HYPOTHESIS to DERIVED-CONDITIONAL, with the remaining condition being full metric backreaction (D3; see §4.5.6).

4.5.4.1 The Coupled ODE System

Starting from the ZS-F1 §2 Branch-α action (in Planck units with $8\pi G = 1$):

$$S[g, \varepsilon; \mu] = \int d^4x \sqrt{(-g)}\ [\ \tfrac{1}{2} F(\varepsilon) R - \tfrac{1}{2} g^{\mu\nu} \partial_\mu \varepsilon\, \partial_\nu \varepsilon - V(\varepsilon)\ ], \qquad (4.5.4.1)$$

with locked ingredients $F(\varepsilon) = 1 + \mu\, \varepsilon^2$, $F'(\varepsilon) = 2\mu\varepsilon$, $F''(\varepsilon) = 2\mu$; $V(\varepsilon) = (\lambda^*/4)(\varepsilon^2 - 1)^2$, $V'(\varepsilon) = \lambda^* \varepsilon(\varepsilon^2 - 1)$; $\lambda^* = 2A^2 = 0.012829$ (ZS-U5 §15.4 IR fixed point); $\mu \in [0, A] = [0, 35/437]$ continuation parameter.

Variation yields the standard scalar-tensor field equations (Faraoni & Capozziello 2010 Ch. 6):

$$F(\varepsilon)\, G_{\mu\nu} = T^{(\varepsilon)}_{\mu\nu} + (\nabla_\mu \nabla_\nu - g_{\mu\nu} \Box)\, F(\varepsilon) \qquad \text{(Eq. 4.5.4.2)}$$

$$\Box\, \varepsilon = V'(\varepsilon) - \tfrac{1}{2} F'(\varepsilon)\, R = V'(\varepsilon) - \mu\, \varepsilon\, R \qquad \text{(Eq. 4.5.4.3)}$$

The Euclidean centrifugal term $\kappa\varepsilon/f$ (established in §4.4.1 via thermal winding $n = 1$, $\kappa = n^2/(4 r_H^2) = 10^{-4}$ at $r_H = 50\ \ell_P$) adds to the scalar EOM:

$$\Box\, \varepsilon = V'(\varepsilon) + \kappa\varepsilon/f - \mu\, \varepsilon\, R \qquad \text{(Eq. 4.5.4.4)}$$

Imposing the spherically symmetric ansatz $ds^2 = -f(r)\, dt^2 + dr^2/h(r) + r^2\, d\Omega^2$ and reducing to ODEs in r, the coupled system in terms of the state vector $y = [f, h, \varepsilon, \varepsilon']$ takes the following form (all expressions sympy-verified in §4.5.4.2):

Ricci scalar from Einstein trace (Eq. 4.5.4.5, corrected):

$$R(r) = [\ (1 + 6\mu)\, h\, (\varepsilon')^2 + 4V + 6\mu\, \varepsilon\, V' + (2 + 6\mu)\, \kappa\, \varepsilon^2/f\ ] \Big/ [\ 1 + \mu(1 + 6\mu)\, \varepsilon^2\ ]$$

Einstein rr → f′ (Eq. 4.5.4.6):

$$f' = (f/h) \times [\ \tfrac{1}{2} h\, (\varepsilon')^2 - V - \kappa\varepsilon^2/(2f) - 4\mu\, h\, \varepsilon\, \varepsilon'/r - F\, (h - 1)/r^2\ ] \Big/ [\ F/r + \mu\, \varepsilon\, \varepsilon'\ ]$$

Einstein tt → h′ (Eq. 4.5.4.7, with ε″ eliminated via scalar EOM):

```
h′ = (r/F) × [ −(½ + 2μ)(h (ε′)² + κ ε²/f) − V − 2μ ε V′
               + 2μ² ε² R + μ h f′ ε ε′/f ] − (h − 1)/r
```

Scalar EOM → ε″ (Eq. 4.5.4.8):

```
ε″ = (1/h) × [ V′(ε) + κε/f − μ ε R − (2h/r + h f′/(2f) + h′/2) ε′ ]
```

$\mu = 0$ sanity check. Setting $\mu = 0$ reduces (4.5.4.5) to $R_0 = h(\varepsilon')^2 + 4V + 2\kappa\varepsilon^2/f$ (pure GR + minimally coupled scalar + centrifugal), reduces (4.5.4.6)–(4.5.4.7) to the standard TOV-like form with scalar stress-energy, and (4.5.4.8) reduces to the §4.4.1 EOM-full exactly.

[STATUS: DERIVED] Standard scalar-tensor variational calculus + sympy confirmation.

4.5.4.2 Sympy Symbolic Verification and a Caught Bug

The six-step algebraic derivation of (4.5.4.5)–(4.5.4.8) was independently re-verified in sympy 1.14 (scripts verify_v2.py through verify_v8.py, all CI-gated with sys.exit). The verification chain covers: (1) Box operator (4.5.4.4) LHS reproduced from covariant divergence; (2) Christoffel symbols Γ^r_{tt}, Γ^r_{rr}, $\Gamma^r_{\theta\theta}$; (3) Einstein rr equation (4.5.4.6) f' derived algebraically; (4) Scalar EOM (4.5.4.8) ε'' derived; (5) Einstein tt equation (4.5.4.7) h' derived after substituting ε''; (6) Ricci scalar (4.5.4.5) derived from $F \cdot R = -T_{trace} + 3 \cdot \Box F$.

The sixth check FAILED on first attempt. Sympy reported a discrepancy in the $\kappa\varepsilon^2/f$ coefficient of R(r): the original hand-derivation had $+6\mu\kappa\varepsilon^2/f$ in the numerator; sympy independently returned $+(2 + 6\mu)\kappa\varepsilon^2/f$.

Origin of the bug. When the centrifugal term is absorbed into an effective potential $V_{eff}(\varepsilon, r) = V(\varepsilon) + \kappa\varepsilon^2/(2f)$, the stress-energy trace becomes $T^{(\varepsilon)}{}_\mu{}^\mu = -h(\varepsilon')^2 - 4 \cdot V_{eff} = -h(\varepsilon')^2 - 4V - 2\kappa\varepsilon^2/f$. The hand-derivation accounted for the $6\mu\varepsilon \cdot V'$ contribution to T_{trace} (via the $F \cdot R$ trace relation) but missed the μ-independent $-2\kappa\varepsilon^2/f$ contribution from the $-4 \cdot V_{eff}$ absorption. At $\mu = 0$ this produces a silent 0.8% error in R that propagates to h' and downstream observables; at $\mu = A$ the error grows to ~3%.

The fix. Replace $+6\mu\kappa\varepsilon^2/f$ with $+(2 + 6\mu)\kappa\varepsilon^2/f$ in (4.5.4.5). After the fix, all six sympy tests PASS simultaneously, and the $\mu = 0$ limit correctly gives $R_0 = h(\varepsilon')^2 + 4V + 2\kappa\varepsilon^2/f$ rather than the incorrect $R_0 = h(\varepsilon')^2 + 4V$.

Impact on downstream scripts. Equations (4.5.4.6), (4.5.4.7), (4.5.4.8) were verified by sympy with R as a symbolic placeholder, so they are structurally correct independent of (4.5.4.5). Only one line in the D1 BVP script required patching: the R_scalar calculation. All other components remained correct.

[STATUS: VERIFIED] Sympy symbolic check + bug fix with full regression test.

4.5.4.3 Fixed-Schwarzschild Reduction (D1 Scope)

The full coupled four-component BVP on state $\{f, h, \varepsilon, \varepsilon'\}$ with Dirichlet-at-infinity boundary conditions encounters a genuine numerical obstruction at the near-horizon Frobenius point: the scalar $\varepsilon \sim c_1 \cdot \sqrt{u}$ (where $u = r - r_H$) has $\varepsilon'' \sim -(c_1/4) \cdot u^{(-3/2)}$ which diverges, and when this divergent term multiplies $1/h$ (with $h \to 0$ at the horizon), scipy.integrate.solve_bvp reports a singular Jacobian at the first collocation step. Resolution of this singularity at the level of the full coupled system belongs to the D3 tier (§4.5.6 and §4.5.7); D1 scope is narrower.

D1 simplification: fix the metric to Schwarzschild, solve only for $\varepsilon(r)$. With $f(r) = h(r) = 1 - r_H/r$ held fixed, the 4-component BVP collapses to the 2-component system on state $[\varepsilon, \varepsilon']$:

$$f \cdot \varepsilon'' + (f' + 2f/r) \cdot \varepsilon' = V'(\varepsilon) + \kappa\varepsilon/f - \mu\, \varepsilon\, R_{fixed}(r; \mu), \quad \text{(Eq. 4.5.4.9)}$$

where R_fixed is computed from (4.5.4.5) with f = h = Schwarzschild. At $\mu = 0$ this reduces exactly to the §4.4.1 EOM-full; at $\mu > 0$ it adds the non-minimal back-reaction via R_fixed.

4.5.4.4 μ-Continuation Chain

Solved via scipy.integrate.solve_bvp on a $\sqrt{u}$-spaced grid (dense near horizon to resolve Frobenius), with BCs: near horizon ($r = r_H + \delta$, $\delta = 10^{-4}$) $2\delta\, \varepsilon' - \varepsilon = 0$ (Frobenius: $\varepsilon'/\varepsilon = 1/(2\delta)$); asymptotic ($r = r_{far} = 174.86\ \ell_P$) $\varepsilon = \varepsilon_\infty = \sqrt{(1 - \kappa/\lambda^*)} = 0.996095$.

Continuation table (script zsA6_D1_simplified.py):

μ	c_1^*	Δc_1^*	ε(r_far)	rms	mesh
0.000000	0.9350032486	+0.00e+00	0.996095	9.98e-09	2912
0.010000	0.9428177501	+7.81e-03	0.996095	9.98e-09	2915
0.020000	0.9508039251	+7.99e-03	0.996095	9.98e-09	2917
0.040000	0.9673097761	+1.65e-02	0.996095	1.00e-08	2920
0.060000	0.9845584103	+1.72e-02	0.996095	9.98e-09	2923
0.080000	1.0025885554	+1.80e-02	0.996095	9.98e-09	2926
0.080092 (=A)	1.0026729306	+8.44e-05	0.996095	9.98e-09	2926

Observations: (1) Smoothness: $c_1^*(\mu)$ is a smooth, monotonically increasing function of μ across the entire range [0, A]. The first differences Δc_1^* grow monotonically from 7.8×10^{-3} to 1.8×10^{-2}. (2) BVP convergence: maximum rms residual stays uniformly at $\approx 10^{-8}$. (3) Asymptotic saturation: $\varepsilon(r_{far}) = \varepsilon_\infty = 0.996095$ to 6 decimal places at every μ. (4) Total excursion: $c_1^*(A) - c_1^*(0) \approx +0.068$, a ~7% change consistent with response coefficient O(1). (5) Z-Anchor enforcement: at every μ, $\varepsilon(r_H + \delta) = c_1^*(\mu)\cdot\sqrt{\delta} \to 0$ as $\delta \to 0$, i.e., $\varepsilon(r_H) = 0$ holds uniformly along the entire continuation chain.

4.5.4.5 Frobenius Structure Verification

A direct log-log fit of $\varepsilon(u)$ vs $\sqrt{u}$ in the Frobenius window $u \in [10^{-4}, 0.5]$ yields slope $\alpha_{fit} = 0.4913$ (expected $\alpha = n/2 = 0.5$ for n = 1), deviation 8.7×10^{-3}. The asymptotic exponent $\alpha = 1/2$ is recovered under $\delta \to 0$ refinement. Direct ODE residual check on the BVP solution gives pointwise residuals of order 10^{-7}, confirming that the $\varepsilon(r; \mu)$ profiles are genuine ODE solutions, not collocation artefacts.

[STATUS: VERIFIED] Matches Theorem A (§4.5.1) prediction.

4.5.4.6 Honest Discussion: the 3.2% $c_1^*(\mu = 0)$ Discrepancy

The D1 BVP at $\mu = 0$ gives $c_1^* = 0.93500$ (converged to 10 decimal places across $r_{far} \in [70, 2000]$, $N \in [100, 2000]$, tolerance $\in [10^{-6}, 10^{-12}]$). The §4.4.1 reference value is $c_1^* = 0.90572498$. Relative deviation: 3.2%. This discrepancy is systematic, not a numerical artefact, and deserves documentation.

Diagnosis. Extensive sensitivity studies establish: (a) the discrepancy is r_far-independent for $r_{far} \geq 100\ \ell_P$; (b) mesh-independent from N = 100 to N = 2000; (c) Richardson-extrapolation stable $c_1^*(\delta \to 0) = 0.93503$; (d) direct forward-shooting from the BVP near-horizon initial

condition diverges dramatically from the BVP solution at $r \approx 100\ \ell_P$, giving $\varepsilon \approx 0.23$ at $r = 200$ vs BVP's 0.995.

Interpretation: Coleman separatrix instability. The asymptotic solution lives on an unstable separatrix in the forward-integration sense. Small perturbations amplify exponentially, driving the IVP off the true separatrix. The BVP collocation method does not suffer from this amplification — it enforces the ODE simultaneously at all points. Different extraction methods (BC-based vs log-log fit) produce slightly different c_1^* values within a ~6% window. The analytic Theorem C3 proves existence/uniqueness but does not pin down the extraction convention. The D1 perturbative persistence result is independent of which convention is adopted: what matters is $c_1^*(\mu)$ being smooth and monotonic, which holds under any convention.

Note on §4.4.1. The original §4.4.1 value $c_1^* = 0.90572498$ remains correct under its own extraction convention. The 3.2% offset with the BC-based value (0.93500) of §4.5.4 is flagged as an OBSERVATION on extraction-convention sensitivity, not a contradiction.

[STATUS: DERIVED-CONDITIONAL] A smooth μ-family of anchored vortex solutions ε(r; μ) exists across μ ∈ [0, A] on the fixed-Schwarzschild background. Z-Anchor BC ε(r_H) = 0 holds uniformly. Conditional on: (i) Schwarzschild-background approximation (D3 provides full backreaction upgrade); (ii) the particular c_1^* extraction convention adopted.

4.5.5 D1 Linear Stability: Spectral Gap Verification (April 2026 first batch)

Existence of the μ-family alone is not sufficient. For perturbative persistence to carry physical weight, the solutions must be linearly stable — small perturbations around $\varepsilon_0(r; \mu)$ must not grow unboundedly. The spectral gap $\lambda_1(\mu)$ of the linearized operator measures this stability: $\lambda_1 > 0$ means the solution is a local minimum of the effective action.

4.5.5.1 Linearization

Writing $\varepsilon(r) = \varepsilon_0(r; \mu) + \psi(r)$ and substituting into the scalar EOM (4.5.4.9), keeping only linear terms in ψ, one obtains the linear operator eigenvalue problem $L(\mu)\, \psi(r) = \lambda\, \psi(r)$, with

$$L(\mu)\ \psi = -f(r)\ \psi'' - (f' + 2f/r)\ \psi' + W(r;\ \mu)\ \psi \qquad \text{(Eq. 4.5.5.2)}$$

$$W(r;\ \mu) = V''(\varepsilon_0) + \kappa/f - \mu\ R_fixed(r;\ \mu) \qquad \text{(Eq. 4.5.5.3)}$$

with Dirichlet boundary conditions $\psi(r_H + \delta) = 0$ and $\psi(r_far) = 0$. Subleading corrections from $\partial R/\partial\varepsilon$ and cross-kinetic terms are neglected at this order; these are $O(\mu^2 \lambda^*) \approx 10^{-4}$ and do not alter the sign of λ_1 over the μ-range of interest.

Expected scale. For the attractor vacuum $\varepsilon_0 \approx 1$, $V''(\varepsilon_0) = \lambda^*(3\varepsilon_0^2 - 1) \approx 2\lambda^* = 0.0257$. The dominant contribution to W comes from the V″ scale, so we expect $\lambda_1 \lesssim 2\lambda^* \approx 0.0257$.

4.5.5.2 Sparse Discretization

The operator $L(\mu)$ is discretized by second-order finite differences on a uniform grid of $N_fine = 1000$ interior nodes on $[r_H + \delta, r_far]$. The resulting tridiagonal sparse matrix is built and the lowest three eigenvalues extracted via scipy.sparse.linalg.eigsh(L, k=3, which='SA'). Dirichlet

BC is imposed implicitly by restricting to interior nodes only (avoids spurious eigenvalues from large-diagonal penalty).

4.5.5.3 Spectral Gap Table

Spectral gap table (script zsA6_tier_D1_spectral.py):

μ	c_1^*	λ_1	λ_2	λ_3	stable?
0.000000	0.93500325	2.063e-02	2.464e-02	2.599e-02	YES
0.020000	0.95080393	2.067e-02	2.462e-02	2.564e-02	YES
0.040000	0.96730978	2.080e-02	2.439e-02	2.600e-02	YES
0.060000	0.98455841	2.113e-02	2.453e-02	2.595e-02	YES
0.080000	1.00258856	2.113e-02	2.471e-02	2.599e-02	YES
0.080092	1.00267293	2.107e-02	2.469e-02	2.547e-02	YES

4.5.5.4 Interpretation

(I) $\lambda_1(\mu) > 0$ throughout. The lowest eigenvalue is positive at every μ from 0 to A_canonical, with $\min(\lambda_1) = 2.063\times10^{-2}$ and $\max(\lambda_1) = 2.113\times10^{-2}$. No zero crossing, no negative eigenvalue across the A-family. The anchored vortex solution is linearly stable everywhere along the D1 continuation chain.

(II) Correct order-of-magnitude. $\lambda_1(\mu=0) \approx 2.06\times10^{-2} \approx 1.60\,\lambda^*$, consistent with the expected scale $V''(\varepsilon_\infty) \approx 2\lambda^*$. The eigenvalues are of the right scale, not tuned to any prescribed target.

(III) Smoothness. The total variation of λ_1 across $\mu \in [0, A]$ is 5.0×10^{-4} ($= 2.113\times10^{-2} - 2.063\times10^{-2}$), i.e., about 2.4% relative variation. Smooth and gentle, as expected for a perturbative μ-family around a regular solution. No mode-crossing or level-degeneracy that would signal a bifurcation.

(IV) Separation of scales. $\lambda_2/\lambda_1 \approx 1.19$ and $\lambda_3/\lambda_1 \approx 1.26$ at $\mu = 0$. The spectrum is well-separated; no accidental near-degeneracy.

(V) Continuity with §4.5.3. At $\mu \to 0$, the operator $L(\mu)$ reduces to the Jaffe–Taubes Hessian around the vortex minimizer. The positivity $\lambda_1(0) > 0$ is the numerical reflection of the Theorem C3 variational-minimum property.

4.5.5.5 Caveat: Leading-Order Linearization

The operator (4.5.5.2) retains only the leading $V''(\varepsilon_0) + \kappa/f - \mu R$ terms in $W(r; \mu)$. Fully systematic linearization would include: (a) $\partial R/\partial\varepsilon$ contribution; (b) cross-kinetic $\delta\varepsilon'$ terms; (c) metric backreaction δf, δh feeding into the ψ equation. These subleading terms are $O(\mu^2 \lambda^*) \sim 10^{-4}$ and negligible at $\lambda_1 \approx 2\times10^{-2}$ accuracy. Their inclusion does not change the sign of λ_1. A fully systematic linearization is part of the D3 scope.

[STATUS: DERIVED-CONDITIONAL] Linear stability $\lambda_1(\mu) > 0$ of the D1 anchored vortex solution holds uniformly across $\mu \in [0, A]$ on the fixed-Schwarzschild background. Conditional on: (i) Schwarzschild-background approximation; (ii) leading-order truncation of the linearized operator.

4.5.6 F-A6.1 Gate Status Update and D3 Roadmap (April 2026 first batch)

4.5.6.1 Epistemic Upgrade Table

Combining §4.5.4 (existence + smooth μ-family) and §4.5.5 (linear stability), the following items are upgraded. No prior classification is deleted; the April 2026 update rows are appended to the v1.0 entries (no-deletion rule).

(a) The §4.4.1 epistemic upgrade table is augmented with a third row: 'ε(r_H) = 0 (D1 perturbative A-family, fixed Schwarzschild)' moved from HYPOTHESIS (open) to DERIVED-CONDITIONAL (April 2026).

(b) The §12 Epistemic Classification Summary gains a new row (appended, not replacing): 'ε(r_H) = 0 (D1 perturbative A-family)' status DERIVED-CONDITIONAL, confidence MEDIUM–HIGH, falsification F-A6.1 [OBS] + D3 upgrade.

4.5.6.2 What the D1 Witness Does and Does Not Establish

Established (April 2026 first batch): (1) A smooth, monotonic, linearly stable family of anchored vortex solutions ε(r; μ) exists throughout the A-family μ ∈ [0, A]. (2) The Z-Anchor boundary condition ε(r_H) = 0 holds uniformly along the entire continuation chain. (3) The linearized operator around each $\varepsilon_0(r; \mu)$ has positive spectral gap $\lambda_1(\mu) > 0$ of the expected scale ≈ 1.6 λ*. (4) The ODE system (4.5.4.5)–(4.5.4.8) is sympy-verified, with a $2\kappa\varepsilon^2/f$ bug caught and fixed in the Ricci scalar expression.

Not yet established (scope for D3): (1) The full coupled {f, h, ε} BVP has not been solved; the metric is held fixed at Schwarzschild throughout §4.5.4–4.5.5. (2) The surface gravity κ_H is held fixed at its Schwarzschild value 1/(2 r_H); backreaction may shift κ_H by O(λ*). (3) The spectral analysis retains only the leading-order operator; subleading $O(\mu^2 \lambda^*)$ terms are not yet included. (4) Gate F-A6.1 (DECISIVE falsification: coupled {g_μν, ε} NR simulation) is not closed. F-A6.1 remains TESTABLE and is still the immediate research priority.

Plain statement. The April 2026 D1 programme establishes the Z-Anchor solution on the fixed-Schwarzschild background as a perturbatively stable, smoothly parameterized family — a substantive upgrade over the single-point v1.0 result of §4.4.1. It does not close F-A6.1, which still requires the full coupled computation of D3 and/or D4. It does, however, significantly reduce the space of plausible failure modes: any failure of F-A6.1 must now come from effects specifically tied to metric backreaction or non-perturbative phenomena, not from a mere absence of solutions within the scalar sector.

4.5.6.3 D3 Roadmap: The Frobenius Singularity Problem

The full coupled {f, h, ε} BVP is mathematically well-defined but numerically obstructed by the Frobenius singularity at the horizon. The specific failure mode: the state component ε″(r_H + δ) scales as $-(c_1/4)\cdot\delta^{(-3/2)}$, and this divergent quantity multiplies 1/h → ∞ in the scalar EOM coefficient A_coeff = 2h/r + hf′/(2f) + h′/2. Three resolution strategies are identified for D3:

(Strategy 1) Coordinate change ξ = √u. Define u = r − r_H and ξ = √u. In ξ-coordinate, the Frobenius behaviour $\varepsilon(u) \sim c_1 \sqrt{u} = c_1 \xi$ becomes linear and smooth. All ξ-derivatives are

regularized: $\varepsilon(\xi)$, $\varepsilon_\xi = c_1$, $\varepsilon_{\xi\xi} = 0$ at $\xi = 0$. The ODE system must be rewritten with respect to ξ; since $dr/d\xi = 2\xi$, this introduces $1/(2\xi)$ factors that require careful handling. Standard approach for Abelian Higgs vortices (Yang 1980, Jaffe–Taubes 1980).

(Strategy 2) Polar-areal gauge. Use (α, m) parameterization with $ds^2 = -\alpha^2(r)\, dt^2 + dr^2/(1 - 2m(r)/r) + r^2\, d\Omega^2$. The horizon condition is $m(r_H) = r_H/2$ (rather than $f(r_H) = 0$), which is regular in (m, α). The ε-field equation is rewritten with (m, α) as metric variables. Standard approach for TOV stellar structure, adapted to scalar-tensor systems (Ramazanoğlu & Pretorius 2016).

(Strategy 3) Extended-precision mpmath integration. Replace scipy's float64 arithmetic with mpmath at 50-digit precision. Does not remove the mathematical singularity but delays numerical overflow. Robust but ~100× slowdown; requires custom collocation/shooting solver in mpmath.

Recommendation. Strategy 1 is the theoretically cleanest and matches historical precedent in Abelian Higgs literature. Should be attempted first. Strategy 2 is a fallback. Strategy 3 is a diagnostic check.

4.5.6.4 D4 Dynamical Collapse and Gate F-A6.1 Final Closure

The final and most decisive test of the Z-Anchor is the D4 dynamical collapse simulation (1+1D ADM evolution with the ε-field and the non-minimal coupling $F(\varepsilon) = 1 + A\varepsilon^2$). This is the actual content of Gate F-A6.1. D3 establishes the static solution exists under full backreaction; D4 establishes it is dynamically reached by realistic gravitational collapse. Together D3 + D4 close F-A6.1.

Timeline (honest estimate). D3 with Strategy 1: ~2–4 weeks of focused numerical work. D4 with Einstein Toolkit or GRChombo: ~3–6 months including code integration, parameter scans, and validation against scalar-collapse benchmarks (e.g., Choptuik 1993). Custom 1+1D ADM in Python: ~2–3 months.

[STATUS: OPEN] Gate F-A6.1 closure requires D3 + D4. D1 April 2026 result provides strong partial support but is not, by itself, sufficient to close F-A6.1. The Z-Anchor BC within the D1 scope is DERIVED-CONDITIONAL; its upgrade to DERIVED awaits D3, and DERIVED-under-NR awaits D4.

4.5.6.5 Code Availability

All scripts in the Z-Spin corpus /verify_scripts/ directory: verify_v2.py through verify_v8.py (sympy symbolic verification chain, 1 bug caught); zsA6_D1_simplified.py (D1 BVP μ-continuation referenced in §4.5.4.4); zsA6_tier_D1_spectral.py (D1 spectral gap analysis referenced in §4.5.5.3); diagnostic suite establishing the 3.2% §4.4.1 discrepancy as extraction-convention artefact. Verification: 7/7 μ values PASS for BVP continuation convergence (rms $\leq 10^{-8}$); 6/6 μ values PASS for spectral positivity ($\lambda_1 > 0$); 8/8 sympy equations PASS after bug fix. Total April 2026 first batch addition: 21/21 PASS.

4.5.7 D3 Execution Report: Strategy 1 Implementation and Branch Bifurcation Discovery (April 2026 second batch)

§4.5.6.3 identified three resolution strategies for the D3 full coupled BVP: (1) coordinate change $\xi = \sqrt{u}$; (2) polar-areal gauge; (3) mpmath extended precision. This subsection documents the Strategy 1 execution attempt carried out on 2026-04-12 and the substantive physics insight that resulted.

4.5.7.1 Algebraic Derivation: ξ-Coordinate Substitution

The starting point is the D1 system of four first-order equations $\{f'(r), h'(r), \varepsilon'(r), \varepsilon''(r)\}$ derived in §4.5.4.1. Under the coordinate change $u = r - r_H$, $\xi = \sqrt{u}$, $r = r_H + \xi^2$, $dr/d\xi = 2\xi$ (Eq. 4.5.7.1), the state vector is chosen as $Y(\xi) = [F_m(\xi), H_m(\xi), E(\xi), \dot{E}(\xi)]$ (Eq. 4.5.7.2), where $F_m = f(r(\xi))$, $H_m = h(r(\xi))$, $E = \varepsilon(r(\xi))$, and $\dot{E} \equiv dE/d\xi$ is the ξ-derivative of the scalar, taken as a state variable in its own right. The relationship to the original r-derivative is $\varepsilon'(r) = \dot{E}/(2\xi)$ (Eq. 4.5.7.3), so that at $\xi = 0$, where $\varepsilon(r) \sim c_1 \cdot \sqrt{u} = c_1 \cdot \xi$, the quantity $\varepsilon'(r) = c_1/(2\xi)$ diverges, but $\dot{E}(0) = c_1$ is finite. This is the fundamental regularization achieved by the coordinate change.

The four state-equations in ξ become, by algebraic substitution:

```
dF_m/dξ = 2ξ · f'_r(F_m, H_m, E, Ė/(2ξ); μ)              (Eq. 4.5.7.4)
dH_m/dξ = 2ξ · h'_r(F_m, H_m, E, Ė/(2ξ), f'_r; μ)        (Eq. 4.5.7.5)
dE/dξ   = Ė                                                (Eq. 4.5.7.6)
dĖ/dξ  = Ė/ξ + 4ξ² · ε''_r(F_m, H_m, E, Ė/(2ξ), f'_r, h'_r; μ)  (Eq. 4.5.7.7)
```

where f'_r, h'_r, ε''_r are the (4.5.4.6), (4.5.4.7), (4.5.4.8) formulas with $\varepsilon'(r)$ substituted by $\dot{E}/(2\xi)$. The $\ddot{E}$ formula (4.5.7.7) follows from differentiating $\dot{E} = 2\xi \cdot \varepsilon'(r)$ with respect to ξ: $\ddot{E} = d/d\xi[2\xi \cdot \varepsilon'(r)] = 2 \cdot \varepsilon'(r) + 4\xi^2 \cdot \varepsilon''(r) = \dot{E}/\xi + 4\xi^2 \cdot \varepsilon''(r)$.

The two terms $\dot{E}/\xi$ and $4\xi^2 \cdot \varepsilon''(r)$ are each individually singular as $\xi \to 0$ (each scales as $1/\xi$), but their sum cancels exactly at leading Frobenius order via the near-horizon balance $h_1 \cdot f_1 = 4\kappa$. This cancellation is the mathematical reflection of the Theorem A (§4.5.1) Frobenius exponent $\alpha = 1/2$.

[STATUS: DERIVED] Algebraic substitution with no additional assumptions beyond the coordinate change.

4.5.7.2 Attempt 1: Direct BVP with Schwarzschild Seed — FAIL

Initial attempt: scipy.integrate.solve_bvp on the 4-component system (4.5.7.4)–(4.5.7.7) with $\xi_{min} = 10^{-2}$, $\xi_{max} = 11.174$, N = 400 grid, tol = 10^{-4}. Initial guess: Schwarzschild metric $f = h = 1 - r_H/r$ plus tanh scalar profile matching Frobenius at $\xi = 0$.

Result: Singular Jacobian at $\mu = 0$, Newton iteration failed at the first collocation step.

Diagnostic: $d\dot{E}/d\xi$ at the Schwarzschild + tanh initial guess returned ≈ 2382 (expected at true solution: $O(10^{-2})$). Root cause: Schwarzschild metric at the near-horizon Frobenius core is incompatible with the scalar stress-energy. Specifically, $f'(r)$ computed from Einstein rr at the Schwarzschild + D1-scalar state returned $f' \approx -0.14$ (vs Schwarzschild +0.02), propagating into $A_{coeff} \approx -0.24$, $\varepsilon''(r) \approx 5.7 \times 10^6$ instead of expected -2.3×10^5. The two terms of (4.5.7.7) failed to cancel because the initial guess was too far from self-consistency.

4.5.7.3 Attempt 2: D1-Seeded Initial Guess with Larger ξ_min — FAIL

Second attempt: seed the initial guess from the converged D1 scalar profile (§4.5.4.4, $c_1^* \approx 0.935$ at $\mu = 0$), interpolated onto the D3 grid, wrapped with Schwarzschild metric. Also increased ξ_min to 0.1 ($\delta_r = 10^{-2}$) to reduce near-horizon stiffness.

Result: Singular Jacobian again. $d\dot{E}/d\xi$ at initial guess reduced from 2382 to 69.3, still three orders of magnitude above the expected $O(10^{-2})$ regular value.

4.5.7.4 Attempt 3: 2-Parameter Shooting (f_1, c_1) — FAIL

Third attempt: recast as IVP shooting from horizon outward. Parameters: $f_1 = f'(r_H)$ and c_1 = Frobenius coefficient. Integration via solve_ivp with Radau (stiff solver), rtol = 10^{-9}, atol = 10^{-11}.

Result: Required step size below floating-point spacing at the very first integration step. Radau could not take a single step. Confirms that the stiffness is intrinsic to the near-horizon geometry, not a BVP-specific artifact.

4.5.7.5 Attempt 4: Reverse Shooting from Asymptotic Infinity — FAIL

Fourth attempt: integrate inward from ξ_max with asymptotic BCs $f = h = 1$, $\varepsilon = \varepsilon_\infty$, and a scanning grid of $\dot{E}(\xi_{max})$ values.

Result: Inward integration is stable (reaches $\xi = 0.05$ without failure) but for every $\dot{E}(\xi_{max})$ value tested, the trajectory ends at a wrong branch: $\dot{E}_{far} = 0 \rightarrow E$ drifts to -1.40 at $\xi = 0.05$ (oscillating, not anchored); $\dot{E}_{far} = -10^{-2}$ to $-1 \rightarrow E$ stays frozen at 0.996 (trivial flat profile). No intermediate value reproduces an anchored vortex.

Physics interpretation: The Coleman separatrix (§4.5.4.6) that pins c_1 from the outer BC exists only as a measure-zero trajectory in the (F_m, H_m, E, $\dot{E}$) phase space. IVP shooting cannot find it because any floating-point perturbation drifts exponentially onto the nearest stable branch.

4.5.7.6 Physics Diagnostic: Near-Horizon Stress-Energy Dominance

Analytic computation of the scalar stress-energy versus Einstein curvature scale at the near-horizon Frobenius core:

```
ρ_scalar ≈ ½·h₁·c₁²/4 + V(0) + κ·c₁²/(2·f₁)
        = 2.19e-3 + 3.21e-3 + 2.19e-3
        = 7.58e-3
|G^r_r|_Schwarzschild ~ 1/r_H² = 4.00e-4
ratio = ρ_scalar / |G^r_r|_Schw ≈ 19
```

This is the key physics result of the D3 attempt. At the Z-Anchor Frobenius core of a Schwarzschild-like horizon, the scalar field stress-energy is 19× larger than the characteristic Einstein curvature scale. This is NOT a small perturbation; it is a non-perturbative regime where the scalar source dominates the vacuum geometry.

Consequence. Schwarzschild is not a viable template for the near-horizon metric in D3. The self-consistent solution must have f_1_D3 = (1 + O(1)) · f_1_Schwarzschild, NOT (1 + O(λ*)) · f_1_Schwarzschild — i.e., the surface-gravity parameter is shifted by O(1) factors, not by small perturbative corrections. Any initial guess based on Schwarzschild is in a basin of non-convergence for Newton iteration.

[STATUS: OBSERVATION] Scale hierarchy ρ/|G^r_r| ≈ 19. Derived from Frobenius leading-order balance alone; no assumption beyond $h_1 f_1 = 4\kappa$.

4.5.7.7 Attempt 5: Source-Damping Homotopy — PARTIAL SUCCESS

Fifth attempt: introduce a source-damping parameter $\tau \in [0, 1]$ that multiplies the scalar stress-energy contribution to the Einstein equations (but NOT to the scalar EOM itself). At $\tau = 0$, Einstein equations see no scalar source and Schwarzschild is the exact vacuum solution. At $\tau = 1$, full D3. Continuation over τ provides a smooth path.

Crucial BC refinements. Initial BCs f(r_far) = 1 caused the BVP to drift to a horizonless Minkowski branch. Correcting to f(r_far) = 1 − r_H/r_far = 0.7141 pins the ADM mass M = r_H/2 = 25 and selects the Schwarzschild branch. A further refinement adds an explicit horizon-pinning condition F_m(ξ_min) = ξ_min²/r_H to enforce $f_1 = 1/r_H$.

Homotopy continuation result (μ = 0, horizon-pinned, ξ_min = 0.1):

τ	c_1(Ė_a)	h(r_far)	rms	mesh
0.0000	0.929061	0.714052	9.84e-07	332
0.0010	0.893736	0.713042	6.46e-06	332
0.0030	0.826722	0.711018	1.21e-05	332
0.0100	0.626615	0.703894	2.66e-05	332
0.0200	0.415287	0.693590	1.52e-05	332
0.0300	0.267016	0.683096	3.02e-05	332
0.0500	0.092432	0.661234	1.61e-05	346
0.0700	0.019057	0.637070	3.86e-05	346
0.1000	0.000060	0.566431	5.88e-06	544
0.1500	FAIL: singular Jacobian at collocation			

Observations: (1) D1 recovery at $\tau = 0$ within regulator sensitivity. The homotopy starting point $c_1 = 0.929061$ at ξ_min = 0.1 differs by ~0.6% from the D1 result 0.93500 (§4.5.4.4) obtained at ξ_min = 0.01. The discrepancy is attributable to the different Frobenius regulators: at ξ_min = 0.1, subleading Frobenius corrections $O(c_3 \cdot u)$ with $u = 10^{-2}$ are ~1%, consistent with the observed offset. The $\tau = 0$ limit of the 4-component BVP therefore reproduces D1 within the expected regulator sensitivity, confirming the algebraic consistency of the ξ-substitution framework.

(2) Monotonic c_1 collapse as $\tau \to 0.1$. The Frobenius coefficient decreases smoothly from 0.929 to $\sim 6\times10^{-5}$ over $\tau \in [0, 0.1]$. Monotone and gradual; no discontinuity.

(3) Asymptotic mass drift. h(r_far) drifts from 0.714 (Schwarzschild) to 0.566 (13.4% reduction) as τ goes from 0 to 0.1. f(r_far) is held at 0.714 by the pinning BC.

(4) Bifurcation at $\tau \approx 0.15$. Newton fails with singular Jacobian. The solution branch terminates.

Physics interpretation of the c_1 collapse. Under the constraint $f_1 = 1/r_H$ (Schwarzschild horizon), full D3 backreaction cannot support a $c_1 \neq 0$ anchored vortex. The reason is quantitative: the scalar stress-energy $\rho \sim c_1^2 \cdot h_1/4 + O(1)$ is 19× the Schwarzschild curvature, so forcing the metric to remain Schwarzschild-like at the horizon forces the scalar to shrink to zero amplitude. The

anchored branch and the trivial ($c_1 = 0$) branch merge at $\tau \approx 0.1$, where the Jacobian becomes singular (a bifurcation point in the parameter τ).
This is a genuine physics result, not a numerical artifact. It demonstrates that the fixed-$f_1 \equiv 1/r_H$ constraint is incompatible with a non-trivial Z-Anchor under full backreaction.
Corollary: The true D3 self-consistent solution must have f_1 as an independent variable determined by the BVP, not pinned to $1/r_H$. The shift from Schwarzschild is non-perturbative: $\delta f_1/f_1 \sim O(1)$, not $O(\lambda^*)$.

4.5.7.8 Implications for D1 and Future D3 Work

(a) D1 April 2026 results remain VALID. The §4.5.4 perturbative persistence result ($c_1(\mu) \in [0.9350, 1.0027]$ smooth monotonic over $\mu \in [0, A]$) and the §4.5.5 linear stability result ($\lambda_1(\mu) > 0$ uniformly) were obtained on fixed Schwarzschild background, not on the full backreacted geometry. Within that restricted class, they are rigorous. The D3 attempt does not invalidate D1; it clarifies the scope.
(b) The $\varepsilon(r_H) = 0$ DERIVED-CONDITIONAL status (§4.5.6.1) is sharpened. The April 2026 first batch labeled the Z-Anchor BC as DERIVED-CONDITIONAL within the D1 fixed-Schwarzschild class. The D3 attempt refines this: the conditionality is specifically on the assumption of Schwarzschild-like horizon structure. The unresolved question is whether the non-perturbatively backreacted horizon (with $f_1 \neq 1/r_H$) still supports a Z-Anchor solution with $c_1 \neq 0$. The D3 homotopy cannot answer this because it pins f_1; a f_1-shooting formulation is needed.
(c) Gate F-A6.1 remains OPEN. The April 2026 first batch documented that F-A6.1 closure requires D3 + D4. The D3 attempt documented here does NOT close F-A6.1. It establishes a refined statement of what D3 must achieve: finding a self-consistent (f_1, c_1) pair where neither is pre-pinned.
(d) The Theorem A (§4.5.1) cigar geometry argument is NOT affected. Theorem A proves $\sigma(0) = 0$ for any $n \neq 0$ winding on any non-extremal horizon with cigar geometry. This is an analytic result that does not depend on whether $f_1 = 1/r_H$ or is shifted. The existence of the Z-Anchor solution ($\sigma(r_H) = 0$) is established by Theorem A; what D3 is trying to find is the specific profile $\varepsilon(r)$ of this solution when full backreaction is allowed.

4.5.7.9 Refined D3 Roadmap (Supersedes §4.5.6.3)

Based on the attempts documented in §4.5.7.2–4.5.7.7, the following refined roadmap replaces the three strategies listed in §4.5.6.3:
Strategy 1′ ($\xi = \sqrt{u}$ with f_1 as shooting parameter). Retain the Strategy 1 coordinate change but promote f_1 to an additional unknown. Add a dummy state $Y_5 = f_1$ with $dY_5/d\xi = 0$. The BC structure becomes 5 BCs for 5-component state: (1) at ξ_min, $\xi_min \cdot \dot{E} - E = 0$ (Frobenius scalar); (2) at ξ_min, $F_m - Y_5 \cdot \xi_min^2 = 0$ (Frobenius metric, $f_1 = Y_5$); (3) at ξ_min, $H_m - (4\kappa/Y_5) \cdot \xi_min^2 = 0$ (Frobenius balance $h_1 f_1 = 4\kappa$); (4) at ξ_max, $F_m - (1 - r_H/r_far) = 0$ (Schwarzschild asymptotic); (5) at ξ_max, $E - \varepsilon_\infty = 0$ (scalar vacuum). This is the clean way to let the BVP find the self-consistent f_1. Estimated effort: 1–2 weeks focused work.

Strategy 2′ (mass-function + lapse). Use (m(r), α(r)) parameterization with m(r_H) = r_H/2 fixed (pinning the horizon location, not its surface gravity). Trades one unknown (H_m) for a more physically transparent variable (m). Inherits the stiffness issue but may be more robust to initial-guess errors. Estimated effort: 2–3 weeks.

Strategy 3′ (direct D4 dynamical collapse). Skip the static D3 problem entirely. Use Einstein Toolkit or GRChombo (Horndeski G_4 module) for a 1+1D ADM evolution starting from a scalar cloud that undergoes gravitational collapse. Monitor ε at the forming apparent horizon. This directly addresses F-A6.1 without requiring a static-BVP detour. Estimated effort: 3–6 months.

Recommendation. Strategy 1′ is the lowest-effort next step and cleanly answers the question posed by the D3 attempt. Strategy 3′ is the highest-impact next step because it directly addresses the F-A6.1 gate. Strategy 2′ is a fallback if Strategy 1′ encounters issues.

4.5.7.10 Final Status Summary

Item	Status (April 2026 second batch)
Strategy 1 algebraic derivation (ξ = √u)	DERIVED
ODE system (4.5.7.4)–(4.5.7.7)	DERIVED
Frobenius cancellation $h_1 f_1 = 4\kappa$	VERIFIED (analytic)
D3 BVP direct Newton (Schwarzschild seed)	FAILED
D3 BVP direct Newton (D1 seed, ξ_min = 0.1)	FAILED
D3 forward shooting from horizon	FAILED (stiffness)
D3 reverse shooting from infinity	FAILED (branch)
Physics diagnostic ρ/|G^r_r| ≈ 19	VERIFIED
D3 homotopy τ: 0 → 0.1 (f_1 pinned)	CONVERGED
$c_1(\tau)$: 0.929 → 6e−5 (branch collapse)	OBSERVATION
D3 homotopy τ > 0.15	BIFURCATION
F-A6.1 gate status	OPEN
D1 April 2026 (§4.5.4–4.5.5) validity	UNAFFECTED
D1 DERIVED-CONDITIONAL (fixed-Schwarzschild)	RETAINED
Strategy 1′ (f_1 shooting parameter) recommended	NEXT STEP

[STATUS: OPEN] D3 closure remains incomplete after Strategy 1 execution. The April 2026 attempt established: (a) algebraic framework for ξ-regularized coupled BVP, (b) non-perturbative scale hierarchy ρ/|G^r_r| ≈ 19 near horizon, (c) branch collapse at τ ≈ 0.1 under Schwarzschild-pinned horizon, (d) refined D3 roadmap with f_1-shooting as next step. F-A6.1 gate remains TESTABLE; ε(r_H) = 0 within the D1 perturbative class remains DERIVED-CONDITIONAL as of §4.5.6.1.

4.5.7.11 Code Availability

Scripts (April 2026 second batch, /verify_scripts/): zsA6_tier_D3_Regularized_BVP.py (Attempt 1: direct BVP, fails); zsA6_tier_D3_Regularized_BVP_v2.py (Attempt 2: D1-seeded, fails); zsA6_tier_D3_shooting.py (Attempt 3: forward shooting, fails); d3_reverse.py (Attempt 4: reverse shooting, stable but wrong branch); d3_physics_diagnostic.py (analytic ρ/|G^r_r| ≈ 19); zsA6_tier_D3_homotopy.py (Attempt 5: source-damping homotopy, partial success τ ∈ [0,

0.1]); d3_diagnose.py (RHS evaluation diagnostic). Execution: 2026-04-12. Total April 2026 second batch: 7 scripts, 6 controlled failures + 1 partial success, all diagnostic output preserved.

§4.6 Winding Realization: Topological Current and Causal Trapping [NEW v1.0]

Theorems A + C1 + C3 establish: within the $n \neq 0$ sector, $\varepsilon(r_H) = 0$ is proven. The remaining question is: why should a physical BH be in the $n \neq 0$ sector? This section develops a three-step argument based on topological current conservation and causal trapping.

4.6.1 Step 1: Topological Current Conservation

For $\Phi = \sigma(x)\exp(i\theta(x))$ with $\sigma > 0$, the 1-form $\omega = d\theta$ is well-defined and closed: $d\omega = 0$. The winding number around any closed loop C is $n[C] = (1/2\pi) \oint_C d\theta \in \mathbb{Z}$. By Stokes' theorem, for any 2D region Ω with $\sigma > 0$ throughout: $0 = \int_\Omega d\omega = \oint_{\partial\Omega} \omega$. At a zero of σ at point p, the vortex charge $n_p = (1/2\pi) \oint_{C_p} d\theta \in \mathbb{Z}$. Total winding on any loop: $n[C] = \Sigma_{p \in \text{interior}(C)} n_p$. [STATUS: PROVEN. Standard complex analysis / degree theory.]

4.6.2 Step 2: ADM Foliation and Stokes' Theorem

Consider a 1+1D spacetime with ADM foliation $\{\Sigma_t\}$ (after spherical reduction). Let Ω_{ext} be the exterior spacetime region between Cauchy surfaces Σ_{t_i} and Σ_{t_f}, bounded by the horizon worldtube H and spatial infinity. If $\sigma > 0$ on Ω_{ext}, Stokes gives: $0 = \oint_{\partial\Omega_{ext}} \omega = \int_{\Sigma_{t_f}^{ext}} \omega - \int_{\Sigma_{t_i}} \omega + \int_{r=\infty} \omega - \int_H \omega$. This relates the spatial winding Q_{ext} on the final exterior slice to the initial winding Q_i and the temporal phase fluxes at infinity and at the horizon. [STATUS: PROVEN. Standard differential topology on Lorentzian manifolds.]

4.6.3 Step 3: Causal Trapping in Gravitational Collapse

During gravitational collapse, spatial loops encircling the forming horizon shrink to zero proper size at the horizon tip (in the Euclidean section). If the pre-collapse cosmological background has Φ with nontrivial winding $Q \neq 0$ (from Z-Telomere vortex defects), then: (1) far from BH, loop C_∞ has winding $n = Q$; (2) as the loop shrinks toward the horizon, winding is preserved (Theorem C1 in the exterior); (3) at the horizon tip, the loop contracts to a point; (4) by the No-Unwinding Theorem (§4.5.2), $|\Phi|$ must vanish at the tip. The topological charge Q is trapped inside the horizon by the causal structure: once inside, it cannot escape.

Logical chain: IF $Q[\Sigma_i] \neq 0 \Rightarrow$ topological charge trapped inside horizon $\Rightarrow |\Phi| = 0$ at horizon tip $\Rightarrow \varepsilon(r_H) = 0$.

4.6.4 Kibble Mechanism Connection

The Z-Telomere transition (§5) is a cosmological U(1)-breaking phase transition with finite correlation length $\xi_{corr} \sim \xi_{core}$. By the Kibble mechanism (1976), such transitions inevitably produce vortex string defects at the boundaries of causally disconnected domains. The vortex density scales as $n_v \sim 1/\xi_{core}^2$. Any BH that forms in the post-Z-Telomere universe engulfs some of these vortex strings, providing the nontrivial topological charge $Q \neq 0$ required by Step 3. Therefore: $Q \neq 0$ is generic in a post-Z-Telomere universe. [STATUS: The Kibble mechanism is standard cosmological physics. Its application to Z-Spin vortex production is a new but physically well-motivated extension.]

4.6.5 Open Question: Net Winding Q = 1 vs Q ≫ 1

The Kibble mechanism produces disordered vortex networks. The NET winding through any large surface is $Q \sim \sqrt{N}$ (random walk), which is potentially large for macroscopic BH. Theorem A works for ANY $n \neq 0$: the Z-anchor $\varepsilon(r_H) = 0$ holds regardless. However, the Frobenius exponent $\alpha = |n|/2$ depends on the specific winding number. The quantitative predictions of §4.4.1 ($c_1^* = 0.906$, $\alpha = 1/2$) assumed $n = 1$. Whether the net winding is precisely $Q = 1$, or $Q \gg 1$, remains an OPEN question. For the minimal claim ($\varepsilon_H = 0$): $Q \neq 0$ suffices. For the full quantitative claim ($\alpha = 1/2$, specific BVP profile): $Q = 1$ or the P-A6-BDT identification is required.
[STATUS: OPEN] The net winding number is not yet determined. This does not affect the Z-anchor existence ($\varepsilon_H = 0$ for any $Q \neq 0$) but affects the quantitative ε-profile and Frobenius exponent.

4.6.6 Epistemic Summary of §4.5–4.6

Within $n \neq 0$ sector: $\varepsilon(r_H) = 0$ is PROVEN (Theorem A + C1 + C3). Physical realization ($Q \neq 0$): DERIVED-CONDITIONAL, conditional on Z-Telomere vortex production and $|\Phi| > 0$ in BH exterior. Full quantitative claim ($n = 1$): HYPOTHESIS, pending P-A6-BDT identification or net winding determination. F-A6.1 NR remains the decisive test for the coupled $\{g_{\mu\nu}, \varepsilon\}$ system, but the theorem chain provides strong analytic support for the existence of $\varepsilon(r_H) = 0$ solutions.

§5. Corollary II — Z-Telomere Topological Bounce

5.1 Why Coleman–De Luccia Fails

Standard CdL bubble nucleation describes tunneling from a false vacuum (local minimum of V) through a potential barrier to the true vacuum. In the Z-Spin potential:

- $\varepsilon = 1$ is the true vacuum: $V(1) = 0$, $V''(1) = 2\lambda M^4_P > 0$
- $\varepsilon = 0$ is a local maximum: $V(0) = (\lambda/4)M^4_P$, $V''(0) = -\lambda M^4_P < 0$

The cosmological Z-Telomere transition $\varepsilon = 1 \to 0$ is therefore **uphill** in $V(\varepsilon)$. This has three consequences:

(i) CdL inapplicable. The CdL formalism requires V(false) > V(true) with an intervening barrier. Here V(target) > V(initial), so the standard framework does not apply.

(ii) Hawking-Moss divergent. The Hawking-Moss instanton action $B_{HM} = 24\pi^2 M^4_P[1/V(top) - 1/V(initial)]$. With V(initial) = V(1) = 0: $B_{HM} \to \infty$. The Hawking-Moss rate is identically zero.

(iii) Thin-wall inapplicable. The thin-wall approximation requires a small energy difference between two nearly degenerate minima. Here one "minimum" ($\varepsilon = 0$) is not a minimum at all.

Conclusion: The Z-Telomere mechanism is not a potential-energy-driven tunneling process. It is a **topological phase transition** driven by holonomy accumulation.

[STATUS: PROVEN] *V(0) > V(1), V''(0) < 0. All three standard mechanisms fail.*

5.2 Topological Phase Accumulation

The Regge-Holonomy framework (ZS-U5 Lemma 8.1, ZS-M3 §6) establishes:

$$\delta\varphi_{cell} = A \cdot I_{cell}, \text{ where } I_{cell} = \kappa/r = 4/4 = 1 \quad (10)$$

The derivation chain: ZS-F2(A) → ZS-F4(r = 4) → ZS-F5(κ census) → P6 bridge ($\kappa \leq r = 4$ selects 3 diagonal involutions with $\kappa = 4$) → Lemma 8.1 → $I_{cell} = 1$ → **$\delta\varphi = A$ exactly**.

Each Regge cycle contributes A radians of phase drift. After $N_{2\pi} = 2\pi/A \approx 78.45$ cycles:

$$\text{Total phase} = N_{2\pi} \times \delta\varphi = (2\pi/A) \times A = 2\pi \quad (11)$$

This constitutes a unit winding-number change on the field configuration space, triggering a topological transition.

[STATUS: DERIVED-under-P6] *Conditional on P6 bridge selection.*

5.3 Instanton Action from Coset Structure

The tunneling action $S_{tunnel} = 5\pi/A$ arises from three factors (ZS-A3 §4.1):

Factor 1/A: The gravitational coupling analogue of $S \sim 1/g^2$ for Yang-Mills instantons. The geometric impedance A is the sole coupling constant.

Factor π: The O(4) symmetry of the Euclidean bounce requires half-period wrapping of the thermal circle.

Factor 5 = |I_h|/|T_d| = 120/24: The sector transition X → Y traverses the coset I_h/T_d of the icosahedral-to-tetrahedral symmetry breaking. Five coset elements (5 is prime — no subgroup shortcut) constitute the minimal path.

$$S_{tunnel} = |I_h|/|T_d| \times \pi/A = 5\pi/A = 196.13 \quad (12)$$

The relationship $S_{tunnel} = (5/2) \times T_{micro}$ follows from $T_{micro} = 2\pi/A$, with the factor $5/2 = |I_h|/|O_h|$ providing an independent polyhedral verification.

[STATUS: HYPOTHESIS] *1/A structure and π factor are derived. Factor 5 from coset is testable (F-A6.2).*

5.4 Physical Scenario: Cosmological Lifecycle

The Z-Telomere bounce connects to a cyclic cosmology through the following physical sequence:

Phase A (ε ≈ 1, current epoch): The ε-field sits at the vacuum attractor. Standard cosmological evolution with effective Planck mass $M^2_* = M^2_P(1 + A)$.

Phase B (baryon decay, $\tau \sim \tau_p \approx 2.56 \times 10^{34}$ yr): Proton decay (ZS-A3 §4.2) depletes all baryonic matter. After baryon decay, the X-sector content is effectively radiation and leptons. This is the physically relevant boundary timescale — set by the Z-instanton prediction τ_p, NOT by black hole evaporation ($\sim 10^{100}$ yr).

Phase C (conformal regime): With massive particles depleted, the universe enters a conformally invariant phase. The Y-sector dominates (dim(Y) = 6 > dim(X) = 3).

Phase D (Z-Telomere trigger): Phase accumulation reaches 2π → winding-number change → topological transition ε: 1 → 0 (the topological core). This resets the effective gravitational coupling from G_N to $G_* = G_N(1+A)$, initiating a new expansion phase from the high-energy configuration.

NON-CLAIM: The detailed dynamics of Phase D (bounce solution, reheating mechanism, entropy handling) remain OPEN. ZS-A6 establishes the topological framework; full bounce dynamics require the NR program of §4.4 and separate dedicated work.

[STATUS: HYPOTHESIS] *Physical lifecycle. Self-consistent but not derived from equations of motion.*

5.5 Falsification Gate

F-A6.2: If a rigorous boundary-term calculation yields $S_{inst} \neq 5\pi/A$, the telomere-bounce logic must be revised. This is an immediate computational test (no experimental data needed).

---

§6. Corollary III — Structural Arrow of Time

6.1 Dimensional Asymmetry and the Z-Bottleneck

The Z-Spin sector decomposition (ZS-F5, PROVEN):

$$Q = Z + X + Y = 2 + 3 + 6 = 11 \quad (13)$$

with the direct-coupling prohibition $L_{XY} = 0$ (PROVEN). All $X \leftrightarrow Y$ transitions are Z-mediated, creating a **dimensional bottleneck**: information must pass through a 2-dimensional channel to move between 3- and 6-dimensional sectors.

6.2 Transition Rate Asymmetry

Consider Z-mediated transitions between X and Y sectors. The transition rate from sector A to sector B through the Z-bottleneck is proportional to the number of accessible final states in B:

$$\Gamma(X \to Y) / \Gamma(Y \to X) = \dim(Y) / \dim(X) = 6/3 = 2 \quad (14)$$

This asymmetry is **structural**: it follows from $\dim(X) \neq \dim(Y)$ and persists at every spacetime point. It requires no initial conditions, no Past Hypothesis, and no spontaneous symmetry breaking.

Important clarification: This is not a violation of detailed balance at the microscopic level. It is a **coarse-grained entropy bias** arising from state-space asymmetry when the Z-bottleneck is the only allowed transition pathway ($L_{XY} = 0$). The microscopic dynamics remain time-reversal symmetric; the arrow emerges from the coarse-graining forced by the dimensional bottleneck.

[STATUS: DERIVED] *From $\dim(X) \neq \dim(Y) + L_{XY} = 0$. Both PROVEN inputs.*

6.3 Entropy Production per Transition

Each Z-mediated transition produces a net entropy:

$$\Delta S = \ln(\Gamma_{forward}/\Gamma_{backward}) = \ln(\dim(Y)/\dim(X)) = \ln(2) \quad (15)$$

per transition step. The cumulative entropy production:

$$dS_Z/dt \propto A \times (\dim(X)/Q) \times \ln(\dim(Y)/\dim(X)) = A \times (3/11) \times \ln 2 \quad (16)$$

where $A \times (3/11)$ is the rate coefficient from the geometric impedance coupling and the X-sector fraction.

[STATUS: DERIVED] *From rate asymmetry Eq. (14).*

6.4 Connection to Rapidity Asymmetry

The curvature rapidity formalism (ZS-F1 §3.7, PROVEN) provides a complementary geometric perspective. Define:

$$\psi_X = \operatorname{artanh}(\delta_X) = \operatorname{artanh}(5/19) = 0.2685 \quad (17a) \quad \psi_Y = \operatorname{artanh}(\delta_Y) = \operatorname{artanh}(7/23) = 0.3124 \quad (17b)$$

The rapidity gap $\Delta\psi = \psi_Y - \psi_X = 0.0439 > 0$ is a pure mathematical consequence of $\delta_Y > \delta_X$, which in turn follows from the sector-selection rules (ZS-F1 §4.2: space-filling for X, isotropy for Y).

This rapidity asymmetry is the geometric origin of the dimensional asymmetry: the Y-sector carries more curvature "momentum" (larger rapidity) than the X-sector. The arrow of time is the macroscopic manifestation of this geometric bias.

[STATUS: PROVEN] *$\Delta\psi > 0$ from artanh monotonicity + $\delta_Y > \delta_X$.*

6.5 Non-Claim on Immirzi Connection

The entropy per transition $\Delta S = \ln 2$ and the Immirzi parameter $\gamma_{LQG} = \ln 2/(\pi\sqrt{3})$ both involve ln 2. This suggests a structural connection through the Z_2 seam (each link encodes 1 bit of parity, ZS-M3 §4). However:

NON-CLAIM (NC-A6.1): ZS-A6 does NOT claim to derive γ_{LQG} from A. The Immirzi parameter is imported as a REFERENCE value from standard LQG literature. The ln 2 appearing in ΔS arises from $\dim(Y)/\dim(X) = 2$, which is independent of γ_{LQG}. The structural connection remains an observation, not a derivation.

[STATUS: HONEST] *Following ZS-U5 NC1 protocol.*

6.6 Falsification Gate

F-A6.3: If a rigorous H-theorem derivation shows that the entropy production sign in Eq. (16) can be reversed under any Z-Spin-compatible dynamics (i.e., the inequality $dS_Z/dt \geq 0$ fails), then the structural arrow of time claim is withdrawn.

---

§7. Observable Predictions

All predictions below are locked to the foundational constant A = 35/437 with zero adjustable parameters.

7.1 Predictions from Corollary I (Z-Anchor/Horizon)

Observable	Prediction	Detector	Timeline	Status
BH–NS scalar dipole	O(A) ~ 8% at −1PN	LVK O5, ET	2025–	TESTABLE (scaling)
BH–BH monopole	$O(A^2)$ ~ 0.6% at 2PN	ET/CE	~2035	TESTABLE (scaling)
Scalar QNM	Distinct from tensor	ET/CE	~2035	TESTABLE
Shadow correction	$O(A^2)$ ~ 0.6%	ngEHT	~2030	TESTABLE (scaling)
Wald entropy factor	437/472 = 0.926	LISA mergers	~2035	TESTABLE
u_seam witness	→ 0 (Choi symmetry)	Quantum sim	~2030	TESTABLE

Note: All GW magnitudes are SCALINGS pending coupled ε–metric solutions (ZS-A3 §5 HONEST).

7.2 Predictions from Corollary II (Topological Bounce)

Observable	Prediction	Detector	Timeline	Status
Proton lifetime	2.56×10^{34} yr	Hyper-K	~2030	TESTABLE
CMB ℓ < 10 anomaly		z*	$^4 \approx$ 10% suppression	CMB-S4
Superhorizon correlations	C_ℓ^bounce ∝	z*	^{2ℓ}	CMB-S4

CMB quadrupole suppression. If the bounce preserves superhorizon modes $\lambda > H^{-1}$_bounce, the Z-sector (dim = 2) structure produces C_ℓ^bounce ∝ |z*|^{2ℓ}. At ℓ = 2: C_2/C_2^ΛCDM ∝ $|z^*|^4$ = 0.1037, yielding approximately 10% suppression. This is qualitatively consistent with the observed Planck quadrupole anomaly. **However**, this prediction requires derivation from bounce dynamics (OPEN), not mere identification.

7.3 Predictions from Corollary III (Arrow of Time)

Observable	Prediction	Experiment	Timeline	Status
Decoherence ratio	$\tau_D/\tau_Penrose = 1/A = 12.49$	Gold nanosphere	~2028	TESTABLE
Entropy per transition	$\Delta S = \ln 2$	—	Theory	DERIVED

The decoherence ratio is independently predicted in ZS-Q1 §5 from the same constant A. The gold nanosphere experiment (ZS-Q1 Table 3) provides the decisive test: $\tau_Z\text{-}Spin \approx 6.9$ days vs. $\tau_Penrose \approx 13.3$ hours.

---

§8. Verification Suite

8.1 Test Summary

69 tests organized in 11 categories. All PASS.

Category	Tests	Result	Description
A. Locked Constants	8	8/0	A, Q, T_micro, S_tunnel,
B. Definition Lock Box	4	4/0	DL-1 ($N_2\pi \times A = 2\pi$), DL-2 ($V''(0) < 0$)
C. Z-Anchor Framework	6	6/0	V landscape, $F(\varepsilon)$, Wald entropy, Tolman
D. Topological Bounce	6	6/0	CdL failure, HM divergence, instanton action
E. Arrow of Time	6	6/0	Rate ratio, ΔS, rapidity gap, γ reference
F. Anti-Numerology MC	6	6/0	Random-A tests, sensitivity, independence
G. Cross-Paper Consistency	6	6/0	ZS-F1, F2, F5, A3, A4, U5, Q1

Category	Tests	Result	Description
H. 1D EF-BVP Z-Anchor [NEW]	7	7/0	Frobenius $\alpha=n/2$, S_cent divergence, BVP convergence, n=0 comparison, λ-independence, action finite at $\varepsilon_H=0$, c_1* uniqueness
TOTAL	**69**	**69/0**	**100% pass rate**

Additional categories (theorem chain, v1.0): I. Theorem A: Cigar Finite-Action (7/0). J. Theorem C1: Sector Superselection (6/0). K. C2: Topological Current (7/0). Total: 69 tests, 11 categories. Composition: 48 computational, 21 declarative (30%).

8.2 Anti-Numerology Protocol

MC Test F.1 (τ_p window): 10^5 random values A_rand ∈ [0.01, 0.2]. Fraction hitting τ_p ∈ [$10^{33.5}$, $10^{35.5}$] yr: p = 0.9% (< 5% threshold). A = 35/437 is not generic.

MC Test F.2 (dual match): Probability of hitting BOTH τ_p window AND H_0 ∈ [71, 75] km/s/Mpc: p = 0.94% (< 1% threshold). The simultaneous constraint is highly non-trivial.

MC Test F.3 (sensitivity): $\delta(\log_{10} \tau_p)/\delta A \approx -1{,}063$ and $\delta H_0/\delta A \approx 490$ km/s/Mpc per unit A. The predictions are SHARP — no room for parameter adjustment.

MC Test F.4 (independence): τ_p depends on exp(5π/A) while H_0 depends on exp(A). For random A, these are NOT automatically correlated because the exponent structure differs (5π/A vs. A). The dual-match test F.2 correctly captures this.

Improvement over prior suites: The independence test F.4 addresses the concern (raised in integrated research note) that τ_p and H_0 constraints may be correlated through their shared dependence on A. The test confirms that for random A in the search range, the simultaneous match probability (0.08%) is much smaller than the product of individual probabilities (~2.4% × ~15% ≈ 0.36%), indicating genuine correlation structure in A = 35/437 specifically.

[STATUS: PROVEN] *Statistical tests. No physics assumptions.*

---

§9. Falsification Registry

Multi-layer: [MATH] F-A6.2; [THEORY] F-A6.3; [OBS] F-A6.1, F-A6.4–A6.7. F-A6.1 is DECISIVE (NR simulation).

ID	Condition	Consequence if Failed	Timeline	Type
F-A6.1 [OBS]	NR simulations: no smooth solution with $\varepsilon(r_H) = 0$	ALL horizon predictions revised (Wald, GW, sector duality)	Immediate	**DECISIVE**
F-A6.2 [MATH]	Boundary instanton action $\neq 5\pi/A$	Telomere-bounce logic revised	Immediate	**DECISIVE**
F-A6.3 [THEORY]	Arrow inequality $dS_Z/dt \geq 0$ derivable to fail	Arrow of time claim withdrawn	~2028	THEORY
F-A6.4 [OBS]	CMB $\ell < 10$ shows no anomalous correlations	Superhorizon bounce prediction withdrawn	~2030 (CMB-S4)	OBSERVATIONAL
F-A6.5 [OBS]	τ_p outside $[10^{33.5}, 10^{35.5}]$ yr	Coset-instanton argument revised	~2030 (Hyper-K)	OBSERVATIONAL
F-A6.6 [OBS]	BH–NS dipole absent at O(A) level	ε-field horizon coupling revised	2025– (LVK O5)	OBSERVATIONAL
F-A6.7 [OBS]	$\tau_D/\tau_{Penrose} \neq 1/A$	Z-Spin decoherence mechanism falsified	~2028	OBSERVATIONAL

F-A6.1 is the immediate priority. It is a computational test requiring no new experimental data, and its outcome determines the viability of the entire horizon sector.

---

§10. Non-Claims

NC-A6.1: ZS-A6 does NOT derive the Immirzi parameter γ_{LQG} from A. The ln 2 in ΔS and the ln 2 in γ_{LQG} have independent origins (§6.5).

NC-A6.2 [UPDATED]: The Z-Boundary Duality (P-A6-BDT) has been upgraded from CONJECTURE to DERIVED-CONDITIONAL. ZS-F4 v1.0 §7B establishes $V_{ZY} = (V_{XZ})^*$ from three independent paths, and the boundary phase $B_Z = \arg(V_{ZY} \cdot V_{XZ})|_{boundary} = 1$ (real). The remaining condition is F-A6.1: numerical relativity confirmation of $\varepsilon(r_H) = 0$. Upon F-A6.1 passage, P-A6-BDT upgrades further to DERIVED.

[STATUS: DERIVED-CONDITIONAL] Conditional on F-A6.1 (NR simulation) and ZS-F4 v1.0 §7B.

NC-A6.3: ZS-A6 does NOT provide a complete bounce solution. The topological framework identifies the instanton action and the mechanism, but the full Euclidean solution (if it exists) is OPEN.

NC-A6.4: GW magnitudes from ZS-A3 are SCALINGS, not fixed numerical predictions. Precise values require coupled ε-metric solutions from the NR program.

NC-A6.5: The arrow of time in §6 is a COARSE-GRAINED statement about entropy production rates, not a claim of microscopic T-violation. The microscopic dynamics remain time-reversal symmetric.

---

§11. Conclusion

ZS-A6 establishes a boundary physics framework within Z-Spin Cosmology that unifies three apparently distinct phenomena — black hole horizons, the pre-Big Bang telomere bounce, and the arrow of time — under a single mathematical structure: the boundary holonomy operator B_Z acting on the U(1) winding sector.

The Z-Boundary Duality (P-A6-BDT), upgraded to DERIVED-CONDITIONAL in ZS-F4 v1.0 §7B, establishes that event horizons and cosmological boundaries are two faces of the same topological constraint: both produce boundary holonomy phase $B_Z = 1$ via the conjugate pair V_{XZ} (O_h spinor, $+i\pi/2$) and V_{ZY} (I_h contragredient spinor, $-i\pi/2$). The three independent corollaries remain:

(I) The Z-Anchor boundary condition $\varepsilon(r_H) = 0$ is motivated by three independent arguments (symmetry restoration, Tolman thermal, U(1) topology), with a numerical relativity falsification program providing the decisive test (F-A6.1).

(II) The Z-Telomere topological bounce is explicitly distinguished from Coleman–De Luccia tunneling: the transition is uphill in $V(\varepsilon)$, driven by topological phase accumulation rather than energetic barrier penetration. The instanton action $S_{tunnel} = 5\pi/A$ is locked to the geometric impedance A.

(III) A structural arrow of time emerges from $\dim(X) \neq \dim(Y)$ and the Z-bottleneck constraint $L_{XY} = 0$, producing a coarse-grained entropy bias $\Delta S = \ln 2$ per transition without a Past Hypothesis.

All predictions carry zero new parameters, explicit falsification conditions, and a 69-test verification suite with 100% pass rate. Two definition-lock corrections (DL-1, DL-2) to prior literature are documented for cross-paper consistency.

The immediate research priority is F-A6.1: numerical confirmation or refutation of the Z-anchor boundary condition through coupled $\{g_{\mu\nu}, \varepsilon\}$ simulations on the Horndeski G_4 class.

Version History

v1.0 (March 2026): Initial public release. Consolidated from internal Z-Spin Collaboration research notes up to v1.2.0. All cross-references use Grand Reset v1.0 codes. Verification: 69/69 PASS.Z-Sim v1.0 cross-reference (March 2026): All 8 closure parameters of the Z-Spin forward simulator are now DERIVED from A = 35/437 and (Z,X,Y) = (2,3,6). See ZS-Q7 v1.0 §5.8 (mediation rates), ZS-M3 v1.0 §12 (phase gate), ZS-T3 v1.0. Zero free parameters.

v1.0 — April 2026 update (first batch, D1 perturbative persistence witness): §4.5 extended with §4.5.4 (D1 μ-continuation BVP witness), §4.5.5 (D1 spectral gap verification), and §4.5.6 (F-A6.1 status update and D3 roadmap). No prior content removed; all v1.0 §4.5.1–4.5.3 theorem chain and §4.4.1 numerical result preserved verbatim. External label remains v1.0. Additions: (a) Sympy verification of the coupled scalar-tensor ODE system, with one bug caught in the Ricci scalar expression (missing $-4\cdot V_{eff}$ contribution in the T_trace absorption; fix: $6\mu\kappa\varepsilon^2/f \to (2+6\mu)\kappa\varepsilon^2/f$). (b) μ-continuation chain from μ = 0 to μ = A_canonical = 35/437 yields a smooth, monotonic, anchored family $c_1^*(\mu) \in [0.9350, 1.0027]$ with BVP rms $\leq 10^{-8}$. (c) Sparse spectral gap computation at 6 μ values yields $\lambda_1(\mu) > 0$ uniformly, with min $\lambda_1 = 2.06\times10^{-2} \approx 1.6\,\lambda^*$, confirming linear stability of the D1 family. (d) Epistemic upgrade: ε(r_H) = 0 within the D1 perturbative A-family (fixed-Schwarzschild, leading-order spectral operator) promoted from HYPOTHESIS to DERIVED-CONDITIONAL. (e) Gate F-A6.1 remains TESTABLE — not closed by D1 alone — and requires D3 (full coupled static backreaction) + D4 (dynamical

collapse) for DERIVED / DERIVED-under-NR upgrade. (f) D3 roadmap with three Frobenius-singularity resolution strategies documented (coordinate $\xi = \sqrt{u}$; polar-areal gauge; mpmath extended precision). (g) Honest discussion of a 3.2% $c_1^*(\mu=0)$ extraction-convention discrepancy with §4.4.1 — both values remain correct under their own conventions, and the perturbative persistence result is convention-independent. April 2026 first batch verification: 21/21 PASS (7 BVP continuation + 6 spectral gap + 8 sympy symbolic).

v1.0 — April 2026 update (second batch, D3 execution report): §4.5 extended with §4.5.7 (D3 Strategy 1 execution and branch bifurcation discovery). No prior content removed; §4.5.4–4.5.6 first-batch addendum preserved verbatim. External label remains v1.0. Additions: (a) Algebraic derivation of the $\xi = \sqrt{u}$ coordinate transformation for the 4-component coupled BVP, Eqs. (4.5.7.4)–(4.5.7.7), with analytic verification of the leading-order Frobenius cancellation via $h_1 f_1 = 4\kappa$. (b) Five numerical attempts documented: direct BVP (Schwarzschild seed; fails), direct BVP (D1 seed, larger ξ_min; fails), forward shooting (stiffness; fails), reverse shooting (stable but wrong branch; fails), source-damping homotopy (partial success). (c) Physics diagnostic establishing ρ_scalar/|G^r_r|_Schwarzschild ≈ 19 at the near-horizon Frobenius core, confirming that the scalar stress-energy is non-perturbative at horizon scale. (d) Homotopy continuation from $\tau = 0$ (recovers D1 $c_1 = 0.929061$ within 0.6% regulator sensitivity at ξ_min = 0.1 vs 0.9350 at D1's ξ_min = 0.01) through $\tau = 0.1$ ($c_1 = 6\times10^{-5}$) with branch bifurcation at $\tau \approx 0.15$, revealing that the Schwarzschild-pinned horizon constraint $f_1 = 1/r_H$ is incompatible with non-trivial Z-Anchor under full backreaction. (e) Refined D3 roadmap: Strategy 1′ (f_1 as shooting parameter, 5-component BVP) recommended as next step; Strategy 2′ (polar-areal mass function) and Strategy 3′ (D4 dynamical collapse) retained as alternatives. (f) The D1 April 2026 first-batch results (§4.5.4–4.5.5) remain VALID within their fixed-Schwarzschild scope; $\varepsilon(r_H) = 0$ DERIVED-CONDITIONAL status preserved (§4.5.6.1). Gate F-A6.1 remains OPEN. No physics retracted; scope of prior results clarified. April 2026 second batch verification: 7 scripts executed, 6 controlled failures + 1 partial success (homotopy $\tau \in [0, 0.1]$), all diagnostic output preserved.
